Abstract

After antibiotic treatment, the pathogen *Clostridium difficile* (*C. difficile*) can colonize a host's gut. It produces the toxins TcdA and TcdB that cause severe diarrhea (Lessa et al., 2015). TcdA/TcdB are internalized via endocytosis into the host cells and are processed in endosomes upon acidification (Pruitt and Lacy, 2012). The present study identifies the chloride/proton antiporter CIC-5 as a player in the intoxication of TcdA in colon cancer cells (HT-29). CIC-5 is a member of the chloride channel family that is situated on endosomes and essential for their acidification (Hara-Chikuma et al., 2005). Here, CIC-5 was located in early and early-to-late endosomes, and colocalized with TcdA. Knockdown of CIC-5 by siRNA significantly lowered the cytopathic effect of TcdA. Vice versa, overexpression of CIC-5 increased internalization of TcdA and was accompanied by lowered endosomal pH values. To proof whether the proton/chloride antiport of CIC-5 is responsible for the increased cytotoxicity of TcdA, the non-transporting E268Q CIC-5 was used. Indeed, TcdA internalization was reduced as compared to WT CIC-5, but increased as compared to control cells. Surprisingly, endosomal acidification was not impaired by this mutant, indicating that CIC-5-mediated acidification of endosomes is independent of its intrinsic transport function. However, CIC-5-promoted endosomal acidification appears to facilitate TcdA intoxication.

Since internalization of proteins depends on endocytosis and subsequent processing of endosomes, the second part of this study established tools to investigate endosomal motility. It focusses on the influence of CIC-5 glycosylation, since multiple CIC-5 mutations with inhibited glycosylation retain the transport in the ER and cause the renal Dent's disease (Scheinman, 1998). The non-complex-glycosylated R516W CIC-5 was chosen as a representative Dent's mutant (Ludwig et al., 2005). Using total internal fluorescence microscopy and particle tracking analysis, this study identified R516W CIC-5 endosomes to move faster along the plasma membrane (PM) and with reduced target-orientation than WT CIC-5. Analysis of two artificial N-glycosylation deficient mutants (N408E and N408A), displayed varying capabilities of endosomal retraction to or from the PM, but indicated that a lack of N-glycans is not the main cause for the altered endosomal mobility of R516W CIC-5.

Keywords: TcdA; CIC-5; endocytosis

Zusammenfassung

Nach Antibiotika-Behandlung kann der Darm eines Patienten vom Pathogen *Clostridium difficile* (*C. difficile*) besiedelt werden. Dieses produziert die Toxine TcdA und TcdB, welche Durchfall verursachen können (Lessa et al., 2015). Die Toxine werden über Endozytose in die Wirtszellen aufgenommen und in Endosomen nach deren Ansäuern prozessiert (Pruitt and Lacy, 2012). In dieser Arbeit wurde der Chlorid/Protonen Austauscher CIC-5 als Mitspieler in der Vergiftung von TcdA identifiziert. CIC-5, ein Mitglied der Familie der Chloridkanäle, befindet sich an Endosomen und ist wichtig für deren Ansäuern (Hara-Chikuma et al., 2005). In dieser Arbeit wurde CIC-5 an frühen und frühen-späten Endosomen detektiert und kolokalisierte mit TcdA. Eine Herunterregulierung des endogenen CIC-5 verringerte die Zytotoxizität von TcdA. Überexpression von CIC-5 führte zu einer erhöhten Internalisierung des Toxins und einem niedrigeren endosomalen pH. Um zu überprüfen ob der Chlorid/Protonen Antiport von CIC-5 die erhöhte Toxizität verursacht, wurde die E268Q CIC-5 Mutante verwendet, welche eine eingeschränkte Transportfunktion besitzt. Diese Mutante internalisierte mehr Toxin als die Kontrolle jedoch weniger als WT CIC-5. Der endosomale pH Wert war durch die Mutation nicht verändert, was darauf hinweist, dass das CIC-5-vermittelte Ansäuern der Endosomen nicht von seiner eigentlichen Transportfunktion abhängt. Das Ansäuern der Endosomen durch CIC-5 scheint somit die Toxizität von TcdA zu erhöhen. Da die korrekte Internalisierung von Proteinen durch Endozytose und somit auch vom Prozessieren der Endosomen beeinflusst wird, wurden im zweiten Teil dieser Studie Methoden entwickelt um die Beweglichkeit von Endosomen zu untersuchen. Der Fokus lag dabei auf dem Einfluss der Glykosylierung von CIC-5, da viele CIC-5 Mutanten, die eine veränderte Glykosylierung aufweisen, und nicht aus dem ER transportiert werden und das renale Dent Syndrom verursachen (Scheinman, 1998). Als repräsentative Dent Mutante diente die nicht-komplex-glykosylierte R516W CIC-5 Mutante (Ludwig et al., 2005). Endosomen der R516W bewegten sich weniger zielorientiert und schneller als der WT entlang der Plasmamembran. Die Analyse von zwei Glykosylierungs-defizienten Mutanten (N408E und N408A) zeigte unterschiedliche Bewegungen was verdeutlicht, dass der Verlust der N-Glykane nicht der hauptsächliche Grund für die veränderte Beweglichkeit ist.

Schlagwörter: TcdA, CIC-5, Endozytose

WT	wild-type

1 Introduction

1.1 The CLC protein family

The family of chloride channel (CLC) proteins comprises proteins that selectively transport anions through membranes. They are conserved from prokaryotes to mammals. In general, CLC proteins are organized as homodimers with each monomer exhibiting a separate ion pathway (= protopore) (Dutzler et al., 2002, 2003; Pusch and Zifarelli, 2014; Tang and Chen, 2011). A monomer is composed of a short NH₂ and COOH (= N- and C-) termini and 18 α -helices (A-R). The helices B-R are membrane-spanning domains (Figure 1 A) (Dutzler et al., 2002, 2003; Feng et al., 2010). Both the N- and C- termini are located intracellularly. The C- terminus of most CLC proteins also harbors two cystathionine β -synthetase (CBS) domains (Fahlke et al., 1997; Jentsch et al., 1999; Mindell et al., 2001). The function of the CBS domains is still poorly understood, but their physiological importance is acknowledged since point mutations in these domains are related to numerous diseases such as osteopetrosis (related to mutations in the CLC-7 protein) (Cleiren et al., 2001; Kornak et al., 2001) or myotonia (caused by mutations in the CLC-1 protein) (Pusch, 2002).

Figure 1: Proposed topology model and crystal structure of a CLC protein (Dutzler et al., 2002; Feng et al., 2010).

A) depicts a topology model of a monomer of a chloride channel based on the *Salmonella enterica serovar* CLC. The monomer is composed of the α -helices A-R and the N- and C- termini. Green and cyan illustrate the two halves of the subunit. Red depicts the regions of the chloride selectivity filter. **B)** illustrates the crystal structure of the cmCLC protein of the red algae *Cyanidioschyzon merolae*. The two monomers are shown in blue and red. The extra- and intracellular domain are depicted as "Out" and "In".

In mammals, the CLC protein family comprises 9 members: CIC-1-7 and CIC-Ka as well as CIC-Kb (as reviewed in Stauber et al., 2012). Initially, all CLC proteins were considered to be chloride channels. However, after the crystallization of the *Escherichia coli* CIC-1 (EcCIC-1), in 2002 (Dutzler et al., 2002), it became clear that not all CLCs were channels. Thus the group of CLCs was divided into chloride channels and chloride/proton antiporters. Now, CIC-1, CIC-2, CIC-Ka and CIC-Kb are described as chloride channels, whereas CIC-3 to CIC-7 are considered chloride/proton antiporters (see Figure 2) (Accardi and Miller, 2004; Picollo and Pusch, 2005; Scheel et al., 2005). One of the main differences between chloride channels and antiporters is that chloride diffuses passively through channels and antiporters are secondary active transporters of chloride and protons. Furthermore, there are differences in the site of expression. Chloride channels are located at the plasma membrane (PM), while transporters localize to intracellular compartments such as early, late and recycling endosomes or lysosomes (Devuyst et al., 1999; Günther et al., 1998; Kornak et al., 2001; Poët et al., 2006; Stobrawa et al., 2001).

Figure 2: Phylogenetic tree of the CLC-protein family (based on Jentsch, 2015; Jentsch et al., 2002; Wills and Fong, 2001).

The CLC protein family is divided into chloride channels and antiporters. CIC-1, CIC-2, CIC-Ka, and CIC-Kb are part of the channel subfamily and CIC-3 to CIC-7 are considered as antiporters. Some CIC-proteins need an accessory subunit. Most of them are expressed in several tissues.

Furthermore, chloride channels seem to be important for the resting membrane potential in skeletal muscle and they are reported to balance the salt transport in the kidney and other tissues (Jentsch, 2008). The chloride transporters are presumably crucial for the acidification of endosomes, lysosomes and other compartments (Graves et al., 2008; Iyer et al., 2002; Kornak et al., 2001, 2006; Piwon et al., 2000; Poët et al., 2006; Stobrawa et al., 2001).

In transporters, each monomer translocates two chloride ions at the expense of one proton through an ion translocation pathway (Alekov and Fahlke, 2009; De Angeli et al., 2006; Zdebik et al., 2008). CLCs are expressed ubiquitously: CIC-1 is mainly expressed in skeletal muscles where it mediates chloride conductance (Lueck et al., 2007; Steinmeyer et al., 1991). CIC-2 is broadly expressed and one of the few chloride channels requiring a β -subunit, GliaCAM, which modulates its functionality (Jeworutzki et al., 2012). CIC-Ka and CIC-Kb are present in the kidney and the stria vascularis of the inner ear. Both chloride channels require barttin as a subunit (Estévez et al., 2001; Uchida et al., 1995). The chloride transporters are all broadly expressed (except for CIC-6). Multiple different functions are ascribed to CIC-3, for instance the volume-regulation in gastric epithelial cells (Jin et al., 2003) or the influence on synaptic transmission in neurons (Guzman et al., 2014). The function of CIC-4 is quite unclear, but an interesting finding suggests that CIC-4 can switch from transporter to a channel-like mode (Alekov and Fahlke, 2009). CIC-5 is required for endosomal acidification but its exact role is still unknown (Hara-Chikuma et al., 2005). CIC-6 is the only chloride transporter which is almost exclusively located to the neuronal system (Poët et al., 2006). The chloride/proton exchanger CIC-7 is the only chloride transporter that needs a subunit for functionality. The protein Ostm1 (osteopetrosis associated membrane protein 1) is essential for the activity of CIC-7 (Lange et al., 2006; Leisle et al., 2011).

Since CIC-5 is located to endosomes and important for the endocytosis, this chloride antiporter was of particular interest in this work. Its structure, function, and mutations in the *CLCN5* genes that are related to disease will be introduced in the following chapters.

1.1.1 The chloride/proton antiporter CIC-5

The chloride/proton antiporter CIC-5 is a member of the CLC antiporter subfamily. CIC-5 is highly expressed in kidney cells, especially in cells of the proximal tubule (PT), the thick ascending limb of Henle's loop and intercalated cells of the collecting duct (Devuyst et al., 1999). Apart from its renal expression, CIC-5 has also been detected in the brain, lung, liver (Steinmeyer et al., 1995), and rat intestinal cells (Vandewalle et al., 2001).

CLC-5 is located on early, late, and recycling endosomes (Christensen et al., 2003a), and to a smaller extent at the PM (Friedrich et al., 1999; Günther et al., 1998). It is important for the regulation of endosomal pH, which is stressed by the loss of CLC-5 that impairs endosomal acidification (Hara-Chikuma et al., 2005). CLC-5 is an electrogenic transporter exchanging two chloride ions by one proton. Thereby, it provides chloride currents over membranes (Picollo and Pusch, 2005). The transport depends on two anion binding sites (S_{cen} and S_{ext}) and two glutamates: a so-called gating glutamate as well as a proton glutamate (E211 and E268, respectively) (see Figure 3 for a model).

The protonatable (pH-sensing) E211 and E268 represent molecular determinants for transport activity. The glutamate site chain E211 opens or close the anion and proton

Figure 3: Model of the ion transport in CLC-5 (modified from Park et al., 2017).

The anti-transport of a CLC transporter of chloride ions (green sphere) and protons (blue sphere) is depicted. Two chloride ions can be bound at the central (S_{cen} , grey dashed circle) and external (S_{ext} , grey dashed circle) anion binding site (a). The unprotonated gating glutamate 211 site chain (purple) can swing between S_{cen} and S_{ext} pushing the chloride into the cytosol (b) and blocking the pathway inhibiting further ion transport. Upon protonation of the proton glutamate 268, protons move to the E211 (c). The protonated E211 then translocates towards the extracellular lumen and chloride ions can bind again to S_{cen} and S_{ext} (d).

pathway in a pH-dependent manner. In detail, the unprotonated E211 can move between the two anion binding sites, thereby inhibiting the chloride binding. When it is located to the extracellular side, two chloride anions can be bound at S_{cen} and S_{ext} . The unprotonated E211 then swings back towards the S_{cen} and the chloride anions are translocated into the cytosol. Protons can then move through the pathway by protonation of the proton glutamate E268 and then transfer to E211.

The protonated E211 swings towards the extracellular lumen and opens the gate for anion translocation. After deprotonation of E211 and translocation of the chloride ions into the cytosol, the proton glutamate swings back, thus closing the gate (Accardi et al., 2005; Grieschat and Alekov, 2012; Park et al., 2017; Smith and Lippiat, 2010).

Electrophysiological studies have shown that CIC-5 is voltage dependent and characterized by strong outward rectifying currents. This means that CIC-5 located to the PM transports chloride into the cell when positive voltages are applied. However, at negative voltages, CIC-5 does not generate any currents (Steinmeyer et al., 1995; Zifarelli and Pusch, 2009).

The coupled transport can be abolished by mutating the proton glutamate at position E268. Mutating the glutamate to an alanine at the corresponding site in EcCIC-1 abolished the proton transport and resulted in a passive chloride channel (Accardi et al., 2005; Lim and Miller, 2009). In CIC-5, the E268Q substitution completely abolished the transport function (Grieschat and Alekov, 2012; Smith and Lippiat, 2010; Zdebik et al., 2008). The transport can be uncoupled by a mutation in the gating glutamate (E211A CIC-5), transforming the antiporter into a pure chloride channel (Accardi and Miller, 2004; Accardi et al., 2004; Picollo and Pusch, 2005; Satoh et al., 2016; Scheel et al., 2005).

As described above, the role of the chloride/proton exchange capability of CIC-5 in endocytosis is of great importance. This was shown in CIC-5 knockout mice which exhibited an impaired receptor-mediated endocytosis of LMW proteins (Piwon et al., 2000; Wang et al., 2000). Yet, its exact role has been debated over the last few years resulting in three different models (illustrated in Figure 4). Initially, CIC-5 was described to ensure acidification of endosomes by providing counter ions for the proton pump V-ATPase (vacuolar-type ATPase) (Devuyst et al., 1999; Lloyd et al., 1996; Picollo and Pusch, 2005; Piwon et al., 2000; Scheel et al., 2005; Wang et al., 2000). Alternatively, it was also proposed that CIC-5 is necessary for direct acidification by exchanging endosomal chloride anions for protons (Picollo and Pusch, 2005; Scheel et al., 2005). Another possibility is that CIC-5's exchange function creates hypotonicity (osmotic pressure) which directly causes activation of the V-ATPase, supporting the chloride shunt model. Using the E211A CIC-5 mutation in mice, which rendered CIC-5 a pure chloride channel, showed an accumulation of chloride in endosomes which led to an impaired acidification but normal endocytosis. Based on this, the researchers concluded that the chloride/proton exchange mode of CIC-5 is necessary to activate the V-ATPase (Satoh et al., 2016).

Figure 4: Proposed functions of CIC-5 in endosomes.

The three different models for the function of CIC-5 in endosomes that were proposed are displayed. The chloride shunt model (**A**), direct acidification model (**B**), and the direct activation of V-ATPase model (**C**). It is established that the V-ATPase is necessary for the acidification of endosomes. It pumps protons from the cytosol into the vesicular lumen (as reviewed in Maxson and Grinstein, 2014). **A**) In the chloride shunt model, CIC-5 pumps chloride ions into the endosome to provide counter ions for the V-ATPase. **B**) The direct acidification model proposes that CIC-5 directly acidifies endosomes by pumping protons into the vesicular lumen. **C**) The direct activation of V-ATPase model supports the chloride shunt model. Satho and coworkers showed that if CIC-5 is mutated to a pure chloride channel (E211A CIC-5), the endosomal acidification is impaired but endocytosis is normal. Based on these findings, they proposed that the chloride/proton exchange mode of CIC-5 activates the V-ATPase.

Besides the different proposed functions of CIC-5, the orientation of the CIC-5 protein in the PM and in endosomes remains paradox (see Figure 5): In heterologous expression systems (for instance in *Xenopus* oocytes or HEK293 cells), CIC-5 is expressed at the PM and in endosomes.

When situated in the PM it exhibits an outward rectification, generating chloride conductance into the cell at positive membrane potentials (Sakamoto et al., 1996; Steinmeyer et al., 1995).

However, Smith and Lippiat were able to demonstrate that CIC-5 is responsible for direct acidification of endosomes independent of the activity of the V-ATPase (Smith and Lippiat, 2010). This raises the (so far unanswered) question if CIC-5 behaves differently in the intracellular environment or if accessory subunits modulate its activity.

Figure 5: The paradox of chloride conductance and transmembrane orientation of CIC-5 (based on George et al., 2001).

The transmembrane orientation of CIC-5 in the PM or in the endosomal membrane is shown. **(A)** Electrophysiological studies demonstrated that CIC-5 transports chloride into the cell upon positive membrane potentials. Negative membrane potentials result in no currents **(B)** CIC-5 is predicted to have different transmembrane orientations in the ER, surface membranes or intracellular vesicles. The branched, black line indicates the extracellular glycosylation site and the amino and carboxyl domains are depicted by short blue lines with knobs.

1.2 The role of CIC-5 in clathrin-mediated endocytosis

Endocytosis describes the process by which extracellular fluid or particles are internalized into the cell. Since CIC-5 is involved in receptor-mediated endocytosis (=clathrin-mediated endocytosis) (Christensen et al., 2003b), the following part will focus on this particular endocytosis mechanism and the role of CIC-5.

In the kidney, the essential function of water and solutes handling depends on the expression, trafficking, and interaction of transport systems (Christensen et al., 2003a; Devuyst and Luciani, 2015). Albumin and other low molecular weight (LMW) proteins are filtered and reabsorbed in the PT. LMW proteins include hormones such as parathyroid or growth hormones, albumin, transferrin, carrier proteins like retinol-binding proteins, enzymes, immunoglobulin light chains, and drugs or toxins (Christensen and Birn, 2002). Their uptake mainly occurs via clathrin-dependent, receptor-mediated endocytosis and involves two receptors: Megalin and cubilin (Christensen et al., 2003a; Dickson et al., 2014; Nielsen and Christensen, 2010). Using purified proteins, Christensen and Bin have shown that the N-terminus of cubilin interacts with megalin upon ligand binding (Christensen and Birn, 2002). After ligand binding and the internalization of receptor and ligand into coated vesicles, the further progression of these endosomes along the endocytic pathway is dependent on acidification of the endosome (Hurtado-Lorenzo et al., 2006). The primary formed vesicles fuse with early endosomes. Then, the internalized substrates are either directly transported to the PM through recycling endosomes, or further processed in late endosomes and finally degraded in lysosomes (Huotari and Helenius, 2011; Mellman, 1996) (see Figure 6).

The acidified environment causes the dissociation of the receptor-ligand complex. It also modulates vesicle trafficking and fusion events with other endosomes (Johnson et al., 1993). The acidification is accompanied by swelling of endosomes. Protons play an important role for the maturation from early to late or recycling endosomes. At the same time, the chloride concentration is a central element. It was shown that the chloride concentration increases from early endosomes (20 - 40 mM) to lysosomes (>80 mM) (Sonawane and Verkman, 2003; Sonawane et al., 2002).

Figure 6: Overview of the endocytosis pathway (modified from Huotari and Helenius, 2011).

Endocytosed particles or substrates are internalized in vesicles. These vesicles then fuse with early endosomes (EE). EE are then either directly transported back to the PM via recycling endosomes, or the endosomes further mature and fuse with late endosomes (LE) and are then degraded in the lysosomes. Rab proteins as marker for specific endosomes are displayed as well (as reviewed in Hutagalung and Novick, 2011).

Renal CIC-5 is mainly expressed in cells of the PT, but also in the thick ascending limb of Henle's loop and a-type intercalated cells of the collecting duct (Devuyst et al., 1999). CIC-5 colocalizes with the proton pump V-ATPase on early endosomes, which transports protons into endosomes for acidification (Devuyst et al., 1999; Günther et al., 1998). Although the role of CIC-5 has been debated, it is established that it plays an important role in the endocytic pathway because a disruption of the *CLCN5* gene in mice causes a reduced endocytosis in PT (Piwon et al., 2000). In order to highlight the importance of CIC-5 in endocytosis, the next paragraph describes its interaction with motor proteins.

1.2.1 Interaction of CIC-5 with motor proteins

CIC-5 positive endosomes are transported along microtubules and this transport requires the interaction with motor proteins. In 2010, Reed and colleagues were able to identify one motor protein that interacts with CIC-5: Kinesin family member B3 (KIF3B), a member of the kinesin 2 subfamily (Reed et al., 2010). In CIC-5 knockout mice and cell cultures, the authors demonstrated that the C-terminus of CIC-5 directly interacted with the coiled-coil (CC) and globular domain (GC) of KIF3B. In addition, KIF3B is important for the transport of CIC-5 to the PM. The C-terminus of CIC-5 is of great importance for the endocytosis and endosomal trafficking, as it has been shown to interact not only with KIF3B but also with cofilin (Hryciw et al., 2003) and Nedd4-2, a member of the neuronal precursor cell-expressed developmentally downregulated 4 protein family (Hryciw et al., 2004). Cofilin is an actin depolymerization factor and promotes actin assembly or disassembly (Andrianantoandro and Pollard, 2006; Bamburg and Bernstein, 2010). Nedd4-2 on the other hand is an ubiquitin-ligase protein (Harvey and Kumar, 1999) that is involved in the regulation of the surface expression of proteins.

Ubiquitination of CIC-5 causes a degradation of the protein as well as its removal from the PM (Schwake et al., 2001). The proposed endocytic model in polarized cells is displayed in Figure 7 (Reed et al., 2010): CIC-5 is located at the apical plasma membrane (APM) with other interacting proteins such as Nedd4-2, NHERF and cofilin (Hryciw et al., 2003, 2004, 2006). Upon binding of a ligand to megalin or cubilin receptors, clathrin coated vesicles are internalized into the cell (Devuyst et al., 1999; Hamm-Alvarez and Sheetz, 1998). Those vesicles contain not only CIC-5 but also CIC-4, a homolog protein of CIC-5 that is broadly expressed in the brain, kidney and muscles (Mohammad-Panah et al., 2003; Stauber et al., 2012). The transport along the microtubules occurs via the Kinesin-2 complex (Hamm-Alvarez and Sheetz, 1998) and the vesicles get acidified and fuse with early endosomes (Jentsch, 2007; Reed et al., 2010).

Figure 7: Transport of ClC-5 positive endosomes along microtubule in polarized cells (from Reed et al., 2010).

Proteins and solutes are resorbed via the receptor-mediated endocytic pathway. After binding to APM receptors (e.g. megalin or cubilin), ligands are internalized together with ClC-5, ClC-4 and other interacting proteins such as Nedd4-2, NHERF2 or cofilin via clathrin-coated vesicles (Hamm-Alvarez and Sheetz, 1998). Endosomes are then transported anterogradely along microtubules via the Kinesin-2 complex. The V-ATPase thus acidifies early endosomes and ClC-5 probably provides counter ions (Piccolo and Pusch, 2005; Scheel et al., 2005)

1.3 ClC-5 in diseases: An overview of a pathogen causing intestinal infection and the hereditary Dent's disease

In this chapter, two diseases will be introduced: an intestinal infection caused by a bacterial enterotoxin and the hereditary Dent's disease. At first glance, both diseases do not seem to have a lot in common. However, in both cases, endocytosis plays an important role in the development and/or progression of the disease.

In general, endocytosis is not only crucial for the survival of cells, but it is also a weak spot for potential pathogens to overcome the membrane barrier, thus promoting their survival or replication. Multiple viruses, such as influenza, Hepatitis B and C viruses, as well as bacteria, i.e. *Listeria monocytogenes* were described to gain access into the host cell by taking advantage of this mechanism (Blanchard et al., 2006; Cooper and Shaul, 2006; Lakadamyali et al., 2004; Veiga and Cossart, 2005). Furthermore, there are bacteria that produce toxins which are internalized via endocytosis. The bacterium *Clostridium difficile* (*C. difficile*) is one of those pathogenic bacteria.

It is one of the most prevalent health-care related pathogens causing severe diarrhea (Papatheodorou et al., 2010). Because CIC-5 is important for endocytosis and toxins of *C. difficile* enter the host's cell via clathrin-mediated and clathrin-independent pathways, it may be possible that CIC-5 plays a role in this intoxication.

Besides pathogens using the cell's endocytosis machinery for their own survival, a disrupted endocytosis can also cause the manifestation of a disease by itself. The hereditary Dent's disease is one example for a disease that is characterized by a deficiency in the endocytosis of albumin and LMW proteins. It is caused by mutations in the *CLCN5* gene (Piwon et al., 2000). Causes and symptoms of the Dent's disease will also be displayed in this chapter.

1.3.1 *Clostridium difficile* and its enterotoxins (TcdA and TcdB)

C. difficile is an anaerobic, spore producing, gram positive bacterium that can cause severe *C. difficile* infection (CDI) (Borriello, 1998; Hall, 1935). In 2011, nearly half a million people suffered from CDI in the United States (Lessa et al., 2015). CDI starts with the ingestion of spores from *C. difficile*, for instance via aerosols, which can cause a colonization of the bacterium in the colon (McFarland et al., 1989). Antibiotic treatment causes a disruption of the normal bacterial gut flora, favoring the bacterium to germinate and colonize. *C. difficile* thus produces toxins inducing diarrhea and colitis. Spores that were produced by the colonizing bacteria exit the host via this route to close the life cycle and spread to new hosts (Martinez et al., 2012; Paredes-Sabja et al., 2014).

The two main virulence factors of *C. difficile* are two large clostridial cytotoxins: TcdA and TcdB (Tcd = toxin of *C. difficile*) (Voth and Ballard, 2005). These exotoxins are proteins with a size of 308 and 270 kDa respectively and comprise several functional domains (Jank and Aktories, 2008) (Figure 8): A receptor binding domain that is composed of C-terminal combined repetitive oligopeptides (CROP), a pore-forming domain, an autoprotease domain, and a translocation (= delivery) domain as well as the N-terminus, which processes a glucosyltransferase domain (GTD) (Genisyuerk et al., 2011).

The genes are encoded in the pathogenicity loci (PaLoc), which contain (apart from *tcdA* and *tcdB*) the *tcdR*, an alternative RNA polymerase sigma factor, controlling the expression of *tcdA* and *tcdB* (Mani and Dupuy, 2001). Two additional genes responsible for the extracellular release and gene repression are also encoded in the PaLoc sequence (Govind and Dupuy, 2012; Govind et al., 2015; Hundsberger et al., 1997; Olling et al., 2012; Tan et al., 2001).

Figure 8: Structure of TcdA (modified from Chumbler et al., 2016).

A) TcdA is comprised of four domains that build the primary structure: the glucosyltransferase domain (GTD, red), the autoprotease domain (APD, purple; including the three-helix bundle, dark purple), the delivery domain (yellow) and the CROPS domain (white). **B and C)** Cartoon representing the TcdA₁₋₁₈₃₂ structure (with the same color code as in a), with zinc shown in green. The CROP domain is not shown.

1.3.1.1 Mode of action of *C. difficile* toxins

The mode of action of the toxins TcdA and TcdB can be briefly described with a four step model (Figure 9): Receptor binding (1), internalization and acidification (2), translocation into the cytosol (3), and glucosylation (= incorporation of glucose) of target proteins (4) (Pruitt and Lacy, 2012). First, the C-terminus of TcdA/B binds to receptors on the surface of the host cell (Dove et al., 1990; von Eichel-Streiber et al., 1992; Florin and Thelestam, 1983). The toxins TcdA and TcdB bind to different receptors. For TcdA, the sucrose-isomaltase and glycoprotein 96 receptors were identified (Na et al., 2008; Pothoulakis et al., 1996), whereas the chondroitin sulfate proteoglycan 4 and poliovirus receptor-like 3 receptors were described as targets for TcdB (LaFrance et al., 2015; Yuan et al., 2015). The binding step is followed by endocytosis and internalization of the toxins. Subsequently, an acidification of the endosome is crucial for the further processing and translocation of the toxins. The acidified environment in endosomes causes the toxins to undergo a conformational change (Barth et al., 2001; Papatheodorou et al., 2010; Voth and Ballard, 2005). The conformational change occurs due to a protonation of two hydrophobic helices and results in the exposure of a hydrophobic region. This probably causes a pore formation in the vesicular membrane (Genisyurek et al., 2011). Finally, the toxins undergo autocatalytic cleavage InsP6-dependent (inositol hexakisphosphate-dependent) and the catalytic subunit of the toxin is released into the cytosol. Then, the toxins GTD domain glucosylates and thereby inactivates its target members of the Ras- homolog (Rho) subfamily (Jank et al., 2007; Just and Gerhard, 2005; Pfeifer et al., 2003; Pruitt et al., 2010).

Rho proteins are small GTPases involved in multiple processes such as regulation of the actin cytoskeleton, cell cycle progression or cell division (BurrIDGE and Wennerberg, 2004; Etienne-Manneville and Hall, 2002). The toxins of *C. difficile* inactivate Rho proteins, such as proteins of the Rac-subfamily, by glucosylation of the Thr35/37 residue (BurrIDGE and Wennerberg, 2004; Just et al., 1995; Yang et al., 2015). This inactivation causes morphological changes due to disorganization of the cytoskeleton and apoptosis (Gerhard et al., 2005; Ottlinger and Lin, 1988), which is probably caused by the disruption of actin cytoskeleton (Bobak et al., 1997; Mahida et al., 1996). Additionally, Rho inhibition induces the caspase-0- and 3-dependent apoptosis (Hippenstiel et al., 2002)

Figure 9: Cellular intoxication process of TcdA and TcdB (from Pruitt and Lacy, 2012).

TcdA and TcdB are composed of four domains as presented in **A**). The N-terminal glucosyltransferase domain (GTD, in red), the “delivery” or pore-forming domain (yellow, it also contains the hydrophobic region in orange), the autoprotease (blue), and the CROPS domain (green) **B**) illustrates the cellular intoxication process as a four steps mode of action: 1) Toxin binding and internalization by receptor-mediated endocytosis. 2) Acidification of endosomes causes a conformation change of the toxin and pore formation. This leads to the release of the GTD into the cytosol (3) by InsP6-dependent autoproteolysis. Finally, the GTD glucosylates Rho family GTPases (4).

Besides the above presented clathrin-dependent internalization of TcdA and TcdB, a clathrin-independent uptake of TcdA has been proposed as well: a truncated TcdA protein, lacking the CROP domain still exhibited cytotoxic properties. Thus, a dynamin-dependent uptake of TcdA was shown for an alternative endocytosis route (Chandrasekaran et al., 2016; Gerhard et al., 2013; Olling et al., 2011).

1.3.2 Dent's disease

Endocytosis is a pivotal cellular mechanism which is not only important for physiological processes but also associated with diseases. On the one hand, pathogens use this mechanism to enter the host's cell thereby causing infections. On the other hand, mutations in proteins involved in endocytosis might result in dysregulation of endocytic processes which can become manifested in severe disorders. One of these diseases is the Dent's disease which can be caused by a mutation in the *CLCN5* gene.

Dent's disease is a tubulopathy first described in 1964 (Dent and Friedman, 1964). It is a rare, recessive, X-linked renal disorder. So far, only members of around 250 families have been described to suffer from Dent's disease (Devuyst and Thakker, 2010). The disease is characterized by a malfunction of solute handling: The main symptoms are nephrocalcinosis, hypercalciuria and LMW proteinuria (Scheinman, 1998). In addition, aminoaciduria, phosphaturia, glycosuria, uricosuria, kaliuresis and impaired urinary acidification were found in affected individuals (Wrong et al., 1994). In men, some symptoms are more manifested than in woman. For instance, 99 % of male patients have LMW proteinuria compared to 70 % of female patients. 96 % of male Dent's patients also show hypercalciuria whereas only 50 % of affected females suffer from this symptom. Around 75% of affected men show nephrocalcinosis and a lower percentage has end stage renal failure (30 – 50 %). While these effects are extremely rare in women (only one female Dent's disease patient was reported to suffer from end stage renal failure) (Scheinman, 1998; Sethi et al., 2009; Wu et al., 2009).

Dent's disease is divided into type 1 and type 2 (Dent-1 and Dent-2) differing with regard to mutated genes and level of manifestation of symptoms in patients (Bökenkamp and Ludwig, 2010; Wrong et al., 1994). Mutations in the chloride transporter *CLCN5* gene are related to Dent-1. Mutations in the *OCRL* (oculocerebrorenal syndrome of Lowe) gene encoding for the phosphatidyl inositol 4,5-bisphosphate 5-phosphatase are typical for Dent-2. As described by Lloyd and colleagues, the majority of *CLCN5* gene mutations found in patients with Dent's disease are nonsense or missense mutations (listed in Table 1) (Lloyd et al., 1996) and occur in the transmembrane domain of the protein (see Figure 10) (Pusch and Zifarelli, 2014). Multiple other mutations that can cause Dent's disease are associated with the carboxyl terminus of ClC-5 (Lloyd et al., 1997; Wu et al., 2003).

Table 1: List of mutations detected in Dent-1 patients (based on Lloyd et al., 1996)

Mutation	carriers
Nonsense	36 %
Missense	33 %
Frameshift deletion	14 %
Frameshift insertion	5 %
Donor splice site	3 %
Acceptor splice site	3 %
Intragenic deletion	2 %
Novel splice site	1 %
Complete deletion	1 %
In-frame insertion	1 %
In-frame deletion	1 %

Figure 10: Dimeric structure of a chloride antiporter and location of Dent's disease mutations (from Pusch and Zifarelli, 2014).

The crystal structure of the algal cmCLC is presented. The two subunits of the dimer are shown in green and gray (transmembrane domains) or yellow and light gray (cytoplasmic domain). Indicated as red and blue spheres are the positions of CIC-5 missense mutations causing Dent's disease. In magenta, the chloride anions that are bound to S_{ext} and S_{int} are indicated.

Patch clamp recordings of oocytes of *Xenopus laevis* or HEK293 cells revealed that most mutations caused a loss of chloride conductance and mutant transporters were not trafficked to the PM (Lloyd et al., 1996). With regard to the trafficking and acidification, three categories of CIC-5 mutations were proposed based on the abnormalities induced by the mutations: The first category includes mutations that result in proteins which are retained in the endoplasmic reticulum (ER) or result in degradation of CIC-5 proteins. The second group contains CIC-5 mutations with defective endosomal acidification. The last group consists of mutations leading to an altered endosomal distribution of CIC-5 proteins but not to a defective endosomal acidification (Smith et al., 2009).

One Dent mutant is of special interest for this work: The R516W mutant. This missense mutation is located in the region of the dimer interface (Smith et al., 2009). The choice of this mutant was motivated by the fact that it was the one missense mutation with functional currents that had an altered glycosylation pattern, increased ER retention and around 30% smaller currents as compared to the wildtype (WT) (Ludwig et al., 2005).

Glycosylation is a posttranslational modification that occurs in the ER and Golgi. It describes the attachment of sugars to the protein. During maturation, a core glycosylation is attached in the ER. Upon further trafficking into the Golgi, the core glycosylation is replaced by more complex N-glycans resulting in the complex glycosylation (for a review see Bard and Chia, 2016).

In general, CIC-5 was shown to be either mono glycosylated in mice and humans (Jouret et al., 2004), or glycosylated on two sites in *Xenopus laevis* (Schmieder et al., 2007). The N-linked glycosylation appears to be a crucial posttranslational modification for CIC-5 that facilitates the transport to the PM as glycosylation deficient xCIC-5 was found to be degraded faster (Schmieder et al., 2007).

1.4 Aim of the study

Despite the large amount of available data presented in the previous chapters, the molecular mechanisms underlying the physiological function of CIC-5 still remain unclear. The aim of the present thesis is thus to define the importance of CIC-5 for the initial endocytic steps as well as the acidification and motility of intracellular vesicles. Therefore, two particular hypotheses will be examined: First, as CIC-5 plays an important role in the endocytosis pathway, it potentially might be hijacked by pathogens that produce endocytosed enterotoxins. Thus, this research set out to investigate the specific role of CIC-5 for the endocytosis and toxicity of TcdA. Initial experiments performed by Dr. Olling and Prof. Gerhard (Institute for Toxicology, Hannover Medical

Figure 11: Cytopathic effect of TcdA (modified from Ruhe et al., 2017).

A) TcdA concentration-dependent cell rounding of HEK293 cells stably transfected with mCherry (control), CIC-5-mCherry, and E268Q-CIC-5-mCherry. **B)** Concentration-dependent proportion of cell rounding as a result of the cytopathic effect of TcdA. For the analysis, the amount of roundish cells compared to cells with healthy morphology was calculated.

School) already indicated that cells overexpressing CIC-5 or the non-transporting E268Q CIC-5 were more susceptible to TcdA (see Figure 11). Yet, the underlying mechanisms remain unclear.

Second, as presented above, it is established that the posttranslational glycosylation of CIC-5 is

often impaired by hereditary Dent's disease mutants. Hence, it is likely that the vesicular transport along the endocytosis pathway is strongly dependent on the speed of the luminal acidification of these compartments. Consequently, the second research aim was to develop tools to quantify the motility of CIC-5-containing endosomal compartments and elucidating the role of the glycosylation for fine-tuning the maturation of endosomes.

2 Methods

2.1 Cell culture and transfection methods

In this study, human embryonic kidney cells (HEK293 and HEK293T), human colon cancer cells (HT-29), and mardin-darby canine kidney cells (MDCKII) were used. All cells were maintained at 37°C under a 5% CO₂ humidified atmosphere and re-cultured every 2-3 days or seeded for transfection. Confluent cells were washed once with PBS (Lonza, Switzerland), separated by using 0.25% Trypsin-EDTA (Gibco/Life Technologies, USA) and resuspended in medium. The appropriate amount of cells was then transferred into a new petri dish and cultivated to subconfluence (for transfection) or confluence. For fluorescence imaging, cells were seeded on glass cover slips, pre-treated with polys-L-lysine (Sigma-Aldrich, Germany) for 10 min. For total internal fluorescence (TIRF) microscopy, cells were seeded in teflon rings glued to glass cover slips, pre-treated with 25% hydrochloric acid and irradiated to UV light for 1 h. For transiently transfected cells, fluorescence imaging was performed 24-48 h after transfection.

Cultivation and transfection of HT-29 cells

HT-29 cells were cultivated in full medium containing Dulbecco's MEM/ Hams F-12 (Biochrom, Germany), 50 units/ml penicillin/streptomycin (Invitrogen, USA) and 10% FBS (Gibco/Life Technologies, USA) and transfected using the jetPRIME transfection reagent (Polyplus-transfection, France) according to the manufacturer's protocol with the following changes: For a 6 cm petri dish, 2 µg Plasmid DNA were added to 500 µl of jetPRIME buffer. After a brief vortexing step, 4 µl jetPRIME reagent were added to the DNA/buffer mix. This mixture was incubated for 10 min at room temperature (RT) before it was added to the cells. For microscopy, cells were seeded on glass cover slips 12-24 h after transfection.

Cultivation and transfection of HEK293 and HEK293T cells

HEK293 and HEK293T were maintained in Dulbecos minimum Eagle's medium (DMEM, Gibco/Life Technologies, USA), supplemented with 10% FBS (Gibco/Life Technologies, USA), 2 mM L-glutamine and 50 units/ml penicillin/streptomycin (Invitrogen, USA) and transfected using calcium-phosphate precipitation (Graham and van der Eb, 1973).

For a 10 cm petri dish, 500 µl of 250 mM CaCl₂ solution was mixed with 5 µg plasmid-DNA and briefly vortexed. Then 500 µl of 2x HEBS were added dropwise to the DNA/CaCl₂ mixture. After 15 min of incubation at RT, the mix was then added to the cells for transient expression.

Stably transfected HEK293 cells expressing mCherry tagged WT CIC-5 or E268Q CIC-5 and mCherry alone (Hebeisen et al., 2003) were cultivated in minimum Eagle's medium (MEM) (Gibco/Life Technologies, USA), supplemented with 10% FBS (Gibco/Life Technologies, USA) and 900 µg/ml Genitacin (G418, Invitrogen, USA).

Cultivation and transfection of MDCKII cells

Mardin-Darby canine kidney (MDCKII) cells were cultivated in MEM medium (Gibco/Life Technologies, USA) supplemented with 10% FBS (Gibco/Life Technologies, USA) and 900 µg/ml Genitacin (G418, Invitrogen, USA). For transfection, the Lipofectamin 2000 and 3000 transfection reagents (Thermo Fisher Scientific, USA) were used. The manufacturer's protocol was slightly changed: For a 3 cm dish, 2 µg of DNA and 4 µl of Lipofectamine were diluted in 50 µl OptiMEM, subsequently.

2.2 Fixation and mounting of cells

For microscopy, cells were fixed using either methanol or 4% formaldehyde (PFA, Thermo Scientific Pierce, USA) in PBS (Lonza, Switzerland). For the fixation, cells were washed with PBS and incubated in methanol at -20°C for 10 min or 4% PFA in PBS for 20 min at RT. Afterwards, cells were washed three times with PBS to remove residual methanol/ PFA.

For mounting the cells, the glass cover slip containing the fixed cells was carefully dried and then placed upside down on a microscope slide glass covered with 15 µl of Fluoromount-G® (Southern Biotechnologies, USA) and air-dried at RT.

2.3 Microscopy and analysis of images and movies

2.3.1 Confocal Microscopy

In order to visualize the subcellular localization of the proteins of interest, fluorophores were attached to the protein and the fluorescence was visualized in living and fixed cells, using a Spinning disc or Laser Scanning Microscope (LSM). The Spinning disc microscope is equipped with a Yokogawa CSU-XI Spinning disc unit. The different fluorophores were excited using the following wavelengths: mCherry at 561 nm, EYFP at 515 nm and EGFP at 445 nm. For mCherry emission detection, the mCherry bandpass filter of 582-636 nm was used, for EYFP, EGFP, and Atto425 emission detection a bandpass filter between 524-550 nm was used.

For the Zeiss LSM 780 confocal laser scanning microscope, the excitation wavelengths of 488 nm for EGFP or Atto425, 514 nm for EYFP or 561 nm for mCherry were used and emission was recorded between 493-574 nm for EGFP and EYFP and respectively 576-696 nm for mCherry.

2.3.2 Total internal reflection fluorescence microscopy

Total internal reflection fluorescence (TIRF) microscopy is a powerful tool to visualize objects that are situated within a defined field depth close to the site of the glass cover slip (Fish, 2001). It offers the opportunity to study events that occur close to the cell surface e.g. the endocytosis pathway of Rab proteins (Tsuboi and Fukuda, 2006) or the fusion of proteins with the PM (Steyer and Almers, 2001). The theory of TIRF microscopy is illustrated in Figure 12: Light hits a surface (e.g. glass/water interface) in a certain angle and is refracted. At a specific critical angle, the beam is totally reflected from this interface (Fish, 2001). A light beam from a laser that travels through the sample above the critical angle will generate an electromagnetic field that decays exponentially with the distance from the surface. Yet, it is capable of exciting fluorophores near the surface without the interference of fluorescence from objects that are not within the defined field depth. This enables the visualization of objects that are less than 400 nm from the solid surface.

Hence, enables the user to visualize the fluorescence of objects that are very close to the PM, e.g. endosomes (Axelrod, 2001; Konopka and Bednarek, 2008). In this study, an iMIC microscope was used equipped with a polytrope and dichrotome dual emission

Figure 12: Principle of TIRFM (based on Konopka and Bednarek 2008).

Upon a critical angle, the light beam is totally reflected from the surface and can generate an electromagnetic field. This electromagnetic field decays with the distance from the surface, enabling the user to visualize objects close to the solid surface.

extension. As objective, the Plan-Apochromat 63x/1.46 Oil (Zeiss, USA) was used as well as the beam splitter MBS400/514/531/640 (AHF, Analysentechnik, Germany) and the filter set with the beam splitter dichroic 515dcxr, the CFP emitter 466-498 nm, and YFP emitter 511-517 nm. The filters were positioned in an oligochrome rapid filter switch with xenon (150W). The CCD camera recorded the videos. The fluorphore mCherry was excited with 514 nm because for the 560 nm excitation, the needed emission filter was not available.

2.3.3 Colocalization analysis

Dual color fluorescence images of cells transiently expressing two proteins (or intoxicated with TcdA) were subjected to a colocalization analysis in order to validate the amount of overlapping objects. This method was used to indicate similar subcellular distributions of two proteins, e.g. the toxin being situated at the same or similar subcellular compartments like CIC-5, or Rab proteins colocalizing with CIC-5. Firstly, dual color fluorescence images were subjected to linear spectral unmixing to remove fluorescence bleed-through (Zimmermann, 2005) using a MATLAB script kindly provided by A. Zeug (Hannover Medical School). Then, an object based colocalization approach was installed using the Fiji plugin SQUASSH (Rizk et al., 2014). The principle and workflow of the object based colocalization is demonstrated in Figure 13. Based on an intensity threshold and whole fitting, a cell mask outlining the cell in each channel and each frame was identified.

When multiple z-stacks were analyzed, the threshold for the cell mask was set for one z-slide. Also, all cells from one sample were treated with the same threshold. The exact used parameters are listed in Supplementary Table 10. Then, objects in each channel were identified ('object outline image overlay' with objects outlined in red or visualized in random colors ('seg RGB')).

Figure 13: Colocalization workflow of the Fiji plugin SQUASSH (Rizk et al., 2014).

Composite image illustrates the overlay of dual color confocal images of CIC-5-mCherry (in red as original image channel 1) and EGFP-TcdA (in green as original image channel 2). The "cell mask" shows the cell area that was identified based on an intensity threshold. The 'object outline image overlay' represents an overlay of the original image with the detected objects outlined in red. "Seg. RGB" visualizes each object in a different, random color. 'Colocalization' denotes the overlay of detected objects from both channels. All objects from the same channel are associated with a distinct color. The FIJI plugin SQUASSH calculates from the identified regions the number of overlapping objects as well as the overlapping area between the channels.

Finally, the amount of overlapping objects (N) from channel 1 and channel 2 were calculated based on the following two categories: i) Object based colocalization, indicating the amount of colocalizing objects from channel 1 with objects in channel 2 and vice versa. Only objects with an overlap of at least 50% were considered 'colocalizing', ii) size based colocalization which depicts the amount of overlapping areas of colocalizing objects from the different channels. In detail, the object based colocalization analysis counts the number of objects from channel 1 that colocalize with objects from channel 2 (and vice versa) (Figure 14). The colocalization coefficient (C) is thus calculated using the following formula:

$$C_{\text{channel } x} = N_{\text{objects channel } x \text{ colocalizing with objects from channel } y} / N_{\text{objects channel } x}.$$

For the size based analysis, only objects that were "colocalizing" were examined and the amount of pixels (V) that overlap with objects from the other channel was calculated:

$$C_{\text{channel } x} = V_{\text{objects channel } x \text{ colocalizing with objects from channel } y} / V_{\text{objects channel } x}.$$

Figure 14: Schematic explanation of object and size based colocalization analysis

Objects in each channel from a dual color fluorescence image were detected (here, the channels were named "blue" and "green"). The colocalization of objects from channel blue with objects from channel green and vice versa was examined. In order to simplify this overview, the focus will be on the colocalization of channel blue with channel green. For the object based analysis (C_{objects}), the amount of overlapping objects from channel blue with objects from channel green was calculated and divided by the total amount of detected objects in channel blue. Objects were considered colocalizing if at least 50% of the object's area was overlapping. For the blue channel the colocalization coefficient would be: $C_{\text{objects}} = 4/6 = 0.67$. For the size based analysis, only those objects that were considered "colocalizing" in the object based analysis were used. Then the area of overlapping pixels from the blue channel was divided by the total area of pixels from blue objects resulting in the coefficient C_{size} . Thus calculating the area of overlapping pixels in the blue channel would result in approximately $C_{\text{size}} = 0.4$.

2.3.4 Particle Tracking

To analyze the motility of CIC-5 positive endosomes in MDCKII cells, movies obtained from the TIRFM were subjected to particle tracking analysis. Multiple different tracking software tools were tested in the beginning: Particle Tracker 2D/3D (Sbalzarini and Koumoutsakos, 2005) and SpeckleTrackerJ (Smith et al., 2011) which are part of the Fiji/ImageJ platform. Diatrack (Vallotton and Olivier, 2013), SpatTrack (Lund et al., 2014) and utrack2.1.3 (Jaqaman et al., 2008) were tested as well. Due to its efficiency, and the ability to process a large amount of movies in a reasonable amount of time, utrack2.1.3 was chosen for further analyses. The program can read movies, detect particles and link particles to trajectories. It creates a MATLAB file containing information about the movie, particles (such as localization and walk length) and indicates the particles of different frames that are summarized in trajectories. The information about particles and trajectories were then extracted from the previously created MATLAB file using a self-made MATLAB script to put the information into an order that was needed for further processing. A “particle” was defined as one spot (=one endosome) detected in one frame of the movie. The “trajectory” was defined as one particle that is detected in more than one frame of the movie. Based on these definitions, the data was further processed to determine the trajectory’s lifetime, velocity, as well as the displacement using a MATLAB script kindly provided by A. Alekov (Hannover Medical School). The lifetime was defined as the timespan in which a trajectory was detected. Based on the extracted values, the mean velocity of a trajectory was calculated as well as the net displacement, which is the distance traveled by the endosome from the point where it was last detected to its origin. Additionally, the target-orientation of the endosomal walk was calculated, which is value for the net displacement divided by the total distance travelled by the endosome.

2.3.4.1 Analysis of mean square displacement

For the analysis of the mean square displacement ($MSD = \langle r^2 \rangle$), the MATLAB based TrackArt program was used (Matysik and Kraut, 2014). The MSD describes how far a particle moves over a certain time increment τ . Therefore, the position of the trajectory at specific time points is first transformed into the squared position (position = $y^2 + x^2$) (see Figure 15 A and B).

Then the distance travelled in defined time lags are extracted over the whole trajectory and mean values are calculated. In detail, for a time lag of one second, the distance from the first to the second, from the second to the third second is calculated until the second last to the last time point of the trajectory and the mean is calculated. A time lag of two seconds means that the distance from the first to the third, the second to the fourth second and so on is calculated until the end of the trajectory is reached. This formula was used for the calculation of the MSD:

$$\text{MSD}(\tau) = \langle \Delta \mathbf{r}(\tau)^2 \rangle = \langle [\mathbf{r}(t+\tau) - \mathbf{r}(t)]^2 \rangle$$

$\mathbf{r}(\tau)$ is the position of the endosome at the time t

τ is the time lag and $\langle \dots \rangle$ represents the average of the displacement $\Delta \mathbf{r}(\tau) = \mathbf{r}(t+\tau) - \mathbf{r}(t)$.

The larger the time lags the least data points can be calculated resulting in higher SEM for larger time lags. The MSD (r^2) points can then be fitted using a linear MSD fit:

$r^2 = a + b \Delta t$, $b = 4D$. a is the intercept, and D ($\mu\text{m}^2/\text{s}$) is the diffusion coefficient, describing the squared distance that a particle moved per second.

Figure 15: Workflow of the calculation of MSD.

The calculation of the MSD of one representative trajectory is shown. The trajectory is present at specific X and Y coordinates at a precise time point (A). The squared position for each time point was then calculated (B). For the actual MSD calculation, the distance traveled for a specific time interval/lag over the whole trajectory was calculated and fitted (C, linear fit as black line).

Based on the curve progression, four different types of movement have been described (see Figure 16): Normal, active, anomalous or confined diffusion. Normal (or free) diffusion describes the movement of a particle based on free Brownian movement.

Active, on the other hand, describes a motion that is actively transported, e.g., by motor proteins. Anomalous or subdiffusion is a movement among immobile obstacles. In a confined diffusion, the MSD reaches a maximum value for larger time-lags due to limitation of space, which means that the particle's diffusive motion is restricted at larger time lags (in a very visual way, one might imagine this kind of movement as a chained dog that is moving within an area that is restricted by the chain) (Matysik and Kraut, 2014). Because of the crowded environment in cells, the transport along microtubules is most likely to be anomalous (Höfling and Franosch, 2013; Saxton, 1994).

Figure 16: Examples of different progression curves of MSD. There are four different types of MSD curves: active, free, anomalous (or subdiffusion), and confined. Endosomes are most likely to display an anomalous MSD curve

2.4 Biochemical methods

2.4.1 SDS-PAGE

SDS-PAGE was used to evaluate the correct processing of transiently expressed proteins. Here, the expression of WT CIC-5 mCherry in HEK203T and HT-29 cells was examined as well as the expression of R516W, N408E and N408A CIC-5-mCherry in HEK293T cells. First, to extract whole cell proteins, 24 h after transfection, cells were washed twice with PBS and scraped off the petri dishes and resolved in 1 ml PBS. The cells were then washed three times by resuspending them in 1 ml PBS after centrifugation (10 s, 100 x g). The pellet was then dissolved in 100 µl lysis buffer. The suspension was incubated on ice for 45 min with a 10 s vortexing step every 5 min followed by a centrifugation step for 15 min at 13,000 x g at 4°C. The supernatant was transferred into a new collection tube and the amount of proteins was examined using the BCA assay (Thermo Fisher Scientific, USA).

For SDS-PAGE, 30 µg of HEK293T cell lysate and respective 60 µg of HT-29 cell lysate, were diluted with 5x SDS loading dye according to Laemmli. The samples were stacked on a gel containing 4% acrylamide and separated by electrophoresis in a gel containing 10% acrylamide in parallel with 1-2 µl of a molecular weight marker (Spectra Multicolor Broad Range Protein Ladder, Thermo Scientific, USA). The fluorescent bands of the transiently expressed proteins and the molecular weight marker were visualized on a fluorescent scanner (Fusion SL, Vilber Lourma, Germany).

2.4.2 Endo H and PNGase F assay

To examine the glycosylation status of WT, R516W, N408E, and N408A CIC-5-mCherry, the two endoglycosidases EndoH_f and PNGase F (New England Biolabs, England) were used in the following protocol: For the PNGase F digestion, 40 µg of protein lysate were diluted with the appropriate amount of 5x SDS-loading dye and denatured for 20 min at RT. Then 4 µl of 10x glycobuffer 2 were added as well as 4 µl NP40 and 4 µl PNGase F. The mixture was briefly mixed and vortexed and incubated for 1 h at 37°C. For the EndoH_f analysis, 40 µg of protein lysate was also diluted with 5x SDS-loading dye and denatured for 20 min at RT. Then 4 µl of G5-buffer and 3 µl of EndoH_f were added and the mixture was also centrifuged and incubated at 37°C for 1 h. The proportion of glycosylation was thus examined using SDS-PAGE as described in the previous paragraph.

2.5 Measurement of vesicular pH using the ratiometric pH sensitive fluorescent protein pHluorin2

We aimed at measuring the pH of CIC-5 positive vesicles in HEK293T cells transiently co-expressing synapto-pHluorin2 and WT CIC-5-mCherry, or the mutants E268Q, R516W, N408E or N408A CIC-5-mCherry. The pH-sensor pHluorin2 is a ratiometric pH-sensitive GFP-variant. Its excitation spectrum has two peaks at 395 and 475 nm with an emission maximum at 509 nm (Mahon, 2011). Acidification leads to a decrease in the fluorescence intensity of pHluorin2 at an excitation at 395 nm and an increase in fluorescence intensity at the excitation at 475 nm (Figure 17). To ensure a vesicular localization of pHluorin2, it was fused to VAMP-2/synaptobrevin as described before (Alekov, 2015). In detail, cells were analyzed using the workflow depicted in Figure 18.

Single z-stacks were recorded at a Zeiss LSM780 microscope using three different excitation wavelengths: 560 nm for mCherry and 488 as well as 405 nm for the ratiometric protein synapto-pHluorin2.

Figure 17: pH dependent fluorescence emission spectrum of pHluorin2 (modified from Mahon, 2011).

Excitation scans of pHluorin2 expressed in HEK293 cells clamped at indicated pHs.

fluorescence intensity, thus allowing a comparison of cells with different expression levels. In order to calculate the actual pH from the measured ratio, a calibration curve was needed. For this purpose, cells only transfected with synapto-pHluorin2 were incubated for 10 min in pH buffer ranging from pH 6 to pH 8 containing 10 μ M nigericin (a K^+/H^+ ionophore that permeates the cell membrane to ensure equilibration of intra- and extracellular pH). Then, the fluorescence in the two channels (excitations at 488 and 405 nm) was recorded. To determine the F_{488}/F_{405} ratios at the specific pH, cell membrane regions stained with pHluorin2 (as indicated in Figure 18 D) were chosen, encircled and the fluorescence ratio was measured using Fiji ImageJ.

Afterwards, vesicles were detected in the mCherry (= CIC-5) channel using a MATLAB script kindly provided by A. Alekov (Hannover Medical School). Then, the fluorescence intensity of those vesicles was measured in the 488 nm and 405 nm channel, respectively and the mean F_{488}/F_{405} ratio of all endosomes of each cell was determined. Calculating the ratio of F_{488}/F_{405} enabled the experimentator to examine the pH independently on the

Figure 18: Workflow and calibration for analysis of vesicular pH using pHluorin2 (based on Ruhe et al., 2017). **A)** Localization of CIC-5 mCherry (red) and synapto-pHluorin2 (green) in transiently transfected HEK293T cells. **B)** Representative image of vesicles detected by the analysis software (encircled). Particles in the mCherry channel were detected and the fluorescence intensity ratio F_{488}/F_{405} was calculated. **C)** Calibration curve of synapto-pHluorin2. HEK293T cells transiently expressing synapto-pHluorin2 were maintained in solution of specific pH containing 10 μM nigericin. Regions along the plasma membrane were chosen to calculate the F_{488}/F_{405} ratio as depicted in **D)**. $N=11$ cells for pH 6, $n=10$ cells for pH 7 and $n=9$ cells for pH 8.

2.6 Intoxication, labeling, and internalization assay of TcdA

2.6.1 Intoxication of cells with *C. difficile* toxin TcdA

In order to examine the effect of CIC-5 on the internalization of TcdA, cells were intoxicated with the TcdA. The EGFP-tagged and fluorescently untagged TcdA was kindly provided by A. Olling and R. Gerhard (Institute for Toxicology, Hannover Medical School).

Because the toxin is internalized in the host cell via endocytosis, the subcellular localization of TcdA was determined. Furthermore, its colocalization with mCherry-tagged WT CIC-5 or E268Q CIC-5 was analyzed. Therefore, HEK293T or HT-29 cells transiently expressing one of the above mentioned proteins were kept on ice in Leibovitz-L medium to inhibit endocytosis. Then the medium was replaced by Leibovitz-L medium containing 200 nM TcdA-EGFP (or labeled TcdA) and incubated on ice for 45 or 75 min. Internalization was initiated by transferring the cells to 37°C for the indicated time period. Unbound toxin was washed off three times with PBS. For live cell analysis, cells were transferred into Tyrode's solution and the fluorescence was visualized under the microscope. Alternatively, cells were fixed and mounted as described in 2.2.

2.6.2 *C. difficile* toxin internalization assay

To measure the amount of internalized TcdA, the primary amino groups of full length TcdA were labeled using the Atto425 Protein Labeling Kit according to the manufacturer's protocol (as described in section 2.6.32). HEK293 cells stably expressing mCherry, CIC-5-mCherry or E268Q CIC-5-mCherry were incubated on ice in Leibovitz-L medium for 15 min. Then 200 nM of labeled toxin was added for 45 min on ice followed by 5 min at 37°C. The unbound toxin was then washed off three times with PBS. Finally, cells were resuspended in 2 ml Tyrode's solution and the fluorescence of the labeled TcdA was analyzed at 425 nm excitation and an emission of 440–650 nm in a Fluorolog-3 spectrofluorometer (Horiba Jobin Yvon, Germany). Afterwards, the absorbance of the samples was measured at 560 nm using a Victor3 multilable reader (PerkinElmer, USA). To determine the amount of cells in the sample, calibration curves for the absorbance at OD₅₆₀ for each different cell line were performed. Therefore, cells were separated using 0.25% Trypsin-EDTA and resuspended in medium.

After a centrifugation step at 300 x g for 3 min, cells were washed once with PBS and centrifuged again (3 min at 300 x g). The pellet was then resuspended in 3 ml Tyrode's solution and the number of cells was counted using a Neubauer chamber and diluted to the indicated concentrations.

Figure 19: Calibration curve for the absorbance at OD₅₆₀ of HEK293 cells stably overexpressing CIC-5-mCherry, E268Q CIC-5-mCherry, or mCherry alone (based on Ruhe et al., 2017).

Calibration curves of the absorbance at OD₅₆₀. Two dilution series for each cell line were performed. The results shown are means \pm SEM.

2.6.3 Fluorescent labelling of primary amino groups of TcdA

To fluorescently label the primary amino groups of TcdA, the Atto425 Protein Labeling Kit (Jena Bioscience GmbH, Germany) was used following the manufacturer's protocol. In brief, sodium bicarbonate was added to the toxin to a final concentration of 100 mM. Then the labeling dye (0.5 μ g/ μ l solved in Dimethylformamide) was added in a 10:1 ratio of TcdA to labeling dye. The mixture was then incubated for 1 h at RT in the dark on a shaker. Finally, the residual free dye was removed from the labeled toxin using a PD Sephadex G25 spin column (GE Healthcare, Germany) in accordance to the manufacturer's protocol.

2.7 CIC-5 siRNA knockdown

To reduce the endogenous expression levels of CIC-5 in HT-29 cells, the ON-TARGETplus Human CLCN5 (Id: 1184) siRNA SMART pool and as negative control the ON-TARGETplus Non-targeting Pool (Dharmacon, USA) were used. One day before transfection, cells were seeded on glass precoated with Poly-L-lysine (Sigma-Aldrich, USA). Then 10 nM or 20 nM of siCIC-5 and 20 nM of control siRNA were transfected. Medium was changed 24 h after transfection and cells were analyzed three days after transfection. For microscopic analysis of cells intoxicated with TcdA, a plasmid carrying the coding sequence of the leucocyte antigen CD-8 was cotransfected. To verify the knockdown of CIC-5, RNA was extracted using the Isol-RNA Lysis Reagent (5PRIME, Germany). Cells were scraped off the plate and washed once with PBS. Then Isol-RNA Lysis Reagent was added and RNA was extracted according to the manufacturer's protocol. The integrity of the RNA was checked on a 2% agarose gel and its concentration was measured using a Nanodrop Photometer (Thermo Fischer Scientific, USA). To remove genomic DNA contamination, a DNaseI digestion was performed using the RQ1 RNase-Free DNase (Promega, USA) according to the protocol. The cDNA was generated with the AMV First Strand cDNA Synthesis Kit (New England Biolabs, England). Finally, the level of CIC-5 mRNA was analyzed using appropriate forward (CIC-5 forw) and reverse primers (CIC-5 rev) (for primer sequence please refer to Supplementary Table 9). Expression levels were normalized to the housekeeping gene phosphoglycerate kinase 1 (PGK1) (Jacobsen et al. 2014). For PGK1, the forward (PGK1 forw) and reverse primers (PGK1 rev) were used. A quantitative RT-PCR was carried out using PowerUP SYBR Green Master Mix (Thermo Fisher Scientific, USA) in triplicates with CIC-5 and PGK1 primers. The expression levels of CIC-5 were normalized to PGK1 levels and the $2^{-\Delta\Delta C_T}$ was calculated (Livak and Schmittgen, 2001). To analyze the cytopathic effect of TcdA on HT-29 cells with reduced levels of CIC-5, cells were incubated with 3 nM TcdA (3 h at 37°C) 72 h after the transfection, and the percentage of rounded cells to cells with healthy morphology was calculated. To identify HT-29 cells with a high probability of transfection with siRNA, cells were cotransfected with a plasmid encoding the CD8 antigen and incubated before with polystyrene microbeads precoated with anti-CD8 antibodies (Dynabeads M-CD8, Dynal) (Me et al., 1994).

Only cells decorated with microbeads were then analyzed for rounding. To exclude any possible bias by the investigator, the rounding of cells carrying beads was also counted by a non-scientific person in a blinded control test. The outcome of the two tests was identical.

2.8 Endocytosis assay

To examine the rate of receptor-mediated and fluid phase endocytosis in HEK293T cells overexpressing WT CIC-5-mCherry, or R516W, N408E and N408A CIC-5-mCherry, albumin (Sigma Aldrich, USA) labeled with Atto425 NHS-ester and CF488A labeled dextran (Biotium, USA) were used. Cells were transfected with 5 μ g plasmid DNA. 48 h after transfection, cells were firstly starved in serum free medium for 1 h before 50 μ g/ml albumin or dextran were added. Cells were then incubated for 5 min at 37°C before they were washed, trypsinized, and the fluorescence of internalized albumin or dextran was analyzed at 425 nm excitation and an emission of 440 – 650 nm in a fluorolog-3 spectrofluorometer (Horiba Jobin Yvon, Germany). As reference sample for unspecific binding, cells were incubated for 1 min on ice with albumin or dextran and the fluorescence intensities from the 1 min incubation were subtracted from the 5 min incubation samples. To ensure that differences in the fluorescence intensity were not due to differences in cell density, the fluorescence intensity was normalized to the absorbance at OD₇₅₀. To confirm that the cell density was still in the linear portion of the curve, a dilution series was performed (Figure 20).

Figure 20: Cell density curve at OD₇₅₀.

HEK293T cells were counted and the OD₇₅₀ of a dilution series was measured to investigate the linear portion of the density curve. Mean \pm SEM are shown. Two dilution series were performed

3 Results

In the following chapters, the role of CIC-5 in the endocytosis, the toxicity of TcdA and the influence of glycosylation on the trafficking of CIC-5 positive endosomes will be examined.

3.1 CIC-5 promotes toxicity of TcdA in HT-29 cells

As described previously, the toxins of *C. difficile* need to overcome the host's endocytosis machinery in order to gain access to the cytosol (for review see Rupnik et al., 2009). In the first part of this study, the functional relationship between the chloride/proton antiporter CIC-5 and TcdA in the human colon cancer cell line (HT-29) cells was investigated.

3.1.1 CIC-5 is correctly expressed and located on endosomes in HT-29 cells

Because CIC-5 is poorly described in HT-29 cells, it was necessary to first ensure its correct synthesis and processing. Therefore, proteins of the mCherry-tagged CIC-5 were either examined in transiently expressing HT-29 and HEK293T (human embryonic kidney) cells. Whole cell protein lysates were investigated using SDS-PAGE (see Figure

Figure 21: Expression of CIC-5-mCherry in HT-29 and HEK293T cells (modified from Ruhe et al., 2017).

SDS page of protein lysates from HT-29 and HEK293T cells transiently expressing CIC-5 mCherry. On a 10% SDS gel, 60 µg of protein was loaded for HT-29 and 30 µg for HEK293T cells. + indicate the complex glycosylated and * the core- and non-glycosylated form. The first lane shows a fluorescent marker with defined molecular weights of the bands indicated in kD.

21). Two bands between around 90-120 kDa were detected, indicating that the CIC-5 protein is present as a complex (120 kDa) as well as a core- and non-glycosylated (90 kDa, Figure 21, asterisk) protein in both cell lines. Since N-glycosylation is predicted to add only 2.5 kDa to the protein, the used SDS-gel did not allow to distinguish between the core- and the non-glycosylated protein (Kornfeld and Kornfeld, 1985). It is worth noticing, that in HEK293T cells, the complex glycosylated band is less dense than the core-and non-glycosylated band.

At the same time, in HT-29, the complex and core-and non-glycosylated form of the CIC-5 protein appear in a similar manner, indicating that the process of glycosylation is more efficient in HT-29 cells.

Then, the subcellular localization of YFP-tagged CIC-5 in transiently transfected HT-29 cells was investigated with a confocal microscope (see Figure 22). It was predominantly located in endosomes and to a smaller amount at the PM and in an ER-like structure. CIC-5 positive vesicles were highly motile particles with a great variance in size.

Figure 22: Localization of CIC-5-EYFP in HT-29 cells.

A-C) Representative confocal images of HT-29 cells transiently expressing YFP-tagged CIC-5. Single Z- slides are depicted and scale bars represent 10 μm .

3.1.2 Knockdown of CIC-5 decrease cytopathic effect of TcdA

Previous experiments in HEK293 cells stably overexpressing WT or E268Q CIC-5 mCherry showed that these cells were more susceptible towards intoxication of TcdA (and TcdB). Intoxication resulted in an increased cytopathic effect in WT or E268Q CIC-5 overexpressing cells as compared to mock cells (see Figure 11) (Ruhe et al., 2017).

To ensure that the increased cytopathic effects of TcdA on cells expressing CIC-5 were not due to overexpression effects, endogenously expressed CIC-5 mRNA levels were reduced by siRNA targeting human CIC-5 (siCIC-5). The successful knockdown of CIC-5 mRNA in HT-29 cells was first tested using quantitative RT-PCR (qRT-PCR). Levels of CIC-5 were normalized to the housekeeping gene PGK1 (Jacobsen et al., 2014). Levels of CIC-5 mRNA were reduced by 40% and 60% when transfected with 10 or 20 nM siCIC-5, respectively (Figure 23), indicating an efficient downregulation of CIC-5.

Figure 23: Efficacy of CIC-5 mRNA knockdown by small interfering RNA (siRNA) in HT-29 cells (modified from Ruhe et al., 2017).

CIC-5 was knocked down by siRNA targeted against human CIC-5 (siCIC-5). As negative control, non-targeting siRNA was used. The result of the qRT-PCR of HT-29 cells transiently transfected with 20 nM control siRNA or 10 and 20 nM siCIC-5. Relative CIC-5 mRNA levels were measured against PGK1 and normalized to the value of the control cells. Mean values of three experiments \pm SEM are shown.

In a next step, cell rounding as a result of the cytopathic effect of TcdA in CIC-5 knockdown cells was examined. Therefore, cells were transfected with siCIC-5 and pLeu2-CD8 and intoxicated with 3 nM TcdA. In order to distinguish between transfected and untransfected cells, cells were preincubated with magnetic dynabeads which bind specifically to the CD-8 antigene (Figure 24 A). The percentage of roundish cells compared to cells with healthy morphology was then analyzed. The outcome of the cell counting might be influenced by the experimenter. To exclude any possible bias, the cells were also counted by a non-scientific person who was not aware of the nature of the research and the possible outcome. As expected, the results were the same.

Figure 24: CIC-5 knockdown decreases TcdA cytotoxicity (Modified from Ruhe et al., 2017).

Endogenously expressed CIC-5 mRNA was downregulated by siCIC-5. HT-29 cells were cotransfected with pLeu2-CD8 and either 20 nM non-targeting siRNA (control) or with 10 or 20 nM siCIC-5. Cells were intoxicated with 3 nM TcdA and cell rounding as result of the cytotoxic effect was examined. (A) displays representative widefield images of transfected HT-29 cells. Black dots represent IgG-CD8-loaded dynabeads, indicating transfected cells. The percentage of roundish cells is shown in (B). Scale bars represent 40 μ m. n=3 petri dishes. Significance was tested using an one-way Anova with post-hoc Tukey HSD; * p<0.05.

The downregulation of CIC-5 caused a significant decrease in the cytopathic effect compared to cells treated with control siRNA by approximately 10% (Figure 24 B). This indicates that cells without CIC-5 are less sensitive to the toxin and it supports the theory that CIC-5 promotes intoxication effects of TcdA.

3.1.3 CIC-5 is located to early endosomes

Because TcdA is internalized and processed in endosomes (Pruitt and Lacy, 2012), the next aim of this study was to examine the localization of CIC-5 in HT-29 cells in the endosomal pathway. So far, it has been described that CIC-5 is present on early endosomes in rat kidney cells (Günther et al., 1998). To investigate the endosomal presence of CIC-5, its colocalization with different members of the Rab-family was examined. Rab proteins are small GTPases widely used as markers of different endosomal stages (Chavrier et al., 1990; Feng et al., 1995; Urbé et al., 1993): Rab5 and Rab4a for early endosomes (Sönnichsen et al., 2000), Rab7 for late (Feng et al., 2010) and Rab11 for recycling endosomes (Sönnichsen et al., 2000; Ullrich et al., 1996). Three different Rab5 variants were available: The wildtype (WT, cycles between GTP and GDP bound form), dominant negative (DN, locked in GDP conformation) and constitutive active (CA, GTP bound). The GTP bound form of Rab5 has been reported to be more membrane-associated whereas the GDP-bound form is cytoplasmic (Stone et al., 2007). Here, the spatial overlap of CIC-5 with all three Rab5 variants was examined (Figure 25). Since a colocalization of CIC-5 with Rab5CA was already shown in kidney epithelial cells (Günther et al., 1998), Rab5WT and Rab5DN were used as additional controls. In all three cotransfections, CIC-5 was located to small vesicular structures. Rab5WT was also situated on endosomes, Rab5DN was diffusely present and Rab5CA was located on larger vesicular structures (Figure 25 A, C, and E). The images with the overlay indicate greater colocalization of CIC-5 with the Rab5WT and CA. In order to quantify the colocalization, a colocalization analysis was performed, using the Fiji Plugin SQUASSH (Rizk et al., 2014). This analysis allows evaluation of the colocalizing pixels of detected objects in the used fluorescence channels. First, the program identifies objects in both fluorescence channels separately. Then the colocalization coefficient of both channels is calculated in an object and a size based analysis:

For the object based calculation, the amount of overlapping objects from one channel is divided by the total amount of objects in this channel. In the size based analysis, only overlapping objects are considered and the number of colocalizing pixels divided by the total number of object-related pixels in this channel is calculated. The program always gives two values for each analysis: Objects from channel 1 colocalizing with objects from channel 2 and vice versa.

A perfect colocalization would result in a colocalization coefficient of 1 (=100%). For a more detailed and graphical description, please refer to Figure 13 and the section 2.3.3 in the methods part.

The object based analysis in Figure 25 showed that CIC-5 colocalized most strongly with Rab5CA objects (over 30% represented by a colocalization coefficient of 0.3) followed by Rab5WT objects (around 30%). For the DN mutant, only two cells showed a distinct colocalization of CIC-5 with Rab5 objects. Nearly no overlap was detected between CIC-5 objects with Rab5DN objects. This may be a result of the different localization of CIC-5 and Rab5DN (Figure 25 C): CIC-5 is mostly on punctuating structures and Rab5DN is diffusely localized. In the analysis, Rab5DN objects were bigger than CIC-5 objects. The size based colocalization indicated that, in half of the analyzed cells, the area of overlap was also quite small. As mentioned above, the size based colocalization coefficient indicates the area of colocalizing pixels over the total size of objects in the specific channel. The colocalization was defined as “good” if the object based colocalization was similar in both channels and the size based colocalization was high. Since this indicated that both proteins were situated in similar compartments and the localization pattern was also alike. Based on these issues, the colocalization between CIC-5 and Rab5CA was the highest followed by CIC-5 overlapping with Rab5WT. The Rab5DN mutant was overlapping to a smaller amount with CIC-5. Overall, the findings showed a distinct colocalization of CIC-5 with Rab5WT, Rab5CA and a smaller colocalization with Rab5DN, supporting previous findings on the presence of CIC-5 on early endosomes (Günther et al., 1998)

Figure 25: Colocalization of CIC-5 with different mutants of Rab5 (Rab5WT, Rab5CA, and Rab5DN) in HT-29 cells (modified from Ruhe et al., 2017).

A), C), E) Representative dual color confocal images showing the localization of CIC-5-EYFP (green) together with one of the three Rab5 variants: Rab5WT-RFP **(A)**, Rab5DN-mCherry **(C)** or Rab5CA-mCherry **(E)** (all three Rab5s in red). **B), D), F)** Box plot summarizing the results from an object (left) and size based (right) colocalization analysis. Objects in both fluorescence channels were detected and the colocalization coefficients of overlapping objects (object base) and fractions of colocalizing objects (size base) were calculated. The channels were defined as Rab5WT-, Rab5DN-, Rab5CA- and CIC-5 as depicted in **(A)**, **(C)** and **(E)**. N = 6 cells for the RabWT and Rab5DN as well as n=9 cells for Rab5CA cotransfections. Single cells (•), mean (◇), median (—). Scale bars represent 10 μ m.

To further characterize the presence of CIC-5 in the endocytic cycle of HT-29 cells, mCherry tagged CIC-5 was coexpressed with additional endosomal markers (GFP-tagged Rab7, Rab11 and Rab4a) (Figure 26). Rab7 and Rab11 were present in vesicular compartments whereas Rab4a was also located in the cytosol. The object based colocalization was calculated and revealed a distinct overlap between CIC-5 and Rab7 (around 24%, Figure 26 D). In addition, CIC-5 partially overlapped with Rab11 (9%). Only a few Rab4a objects colocalized with CIC-5 objects (4%), but a higher amount of CIC-5 objects overlapped with Rab4a (36%), due to the diffusely located Rab4a.

Overall, the results indicate that CIC-5 was also localized on late, Rab7-positive endosomes and to a very small extend on recycling, Rab11-positive endosomes.

Figure 26: Colocalization of CIC-5 with Rab7, Rab11 and Rab4a in HT-29 cells (modified from Ruhe et al., 2017)

A)-C) Single z-slides of representative confocal images of HT-29 cells cotransfected with CIC-5-mCherry (red) and either Rab7-, Rab11- or Rab4a-EGFP (all in green), respectively. **D)** Box plot summarizing the results from an object based colocalization analysis. Objects in both fluorescence channels were detected and the colocalization coefficients of overlapping objects were calculated. The fluorescence channels were defined as Rab7, Rab11 or Rab4a and CIC-5. N=10 cells for Rab7 as well as n=11 cells for Rab4a and n=16 cells for Rab11. Single cells (•), mean (◊), and median (—). Transfection and microscopy was performed by R. Abromeit, Image processing and colocalization analysis was performed by F. Ruhe.

3.1.4 The non-transporting E268Q CIC-5 is also localized on early endosomes

Endosomal acidification is crucial for the toxicity of *C. difficile* toxins as TcdA and TcdB undergo a conformational change upon acidification (Pruitt et al., 2010; Qa'Dan et al., 2000), finally leading to the release of the enzymatically active N-terminus into the cytosol (Barth et al., 2001; Giesemann et al., 2006; Schwan et al., 2011). There is evidence that CIC-5 promotes endosomal proton accumulation in early endosomes of the proximal tubule (Hara-Chikuma et al., 2005) as well as in HEK293 cells (Smith and Lippiat, 2010). Combining the facts that the toxins need acidification for their conformational change and that CIC-5 promotes acidification led to the theory that the ability of CIC-5 to promote changes in pH might be the cause for the increased susceptibility towards the toxins of *C. difficile*. In order to investigate this idea, the non-transporting mutant E268Q CIC-5 was used. The so called proton-glutamate is neutralized in this mutant. In mammalian cells, this mutation resulted in the loss of proton and chloride transport (Grieschat and Alekov, 2012; Smith and Lippiat, 2010;

Figure 27: Subcellular localization of E268Q CIC-5 in HT-29 cells (modified from Ruhe et al., 2017.

A and B) Representative confocal images (maximum intensity projections) from HT-29 cells transiently transfected with E268Q CIC-5-EYFP. Scale bars represent 10 μm)

Zdebik et al., 2008). The first step was to identify the subcellular localization of the E268Q mutant in HT-29 cells (Figure 28 A and B) followed by the analysis of its colocalization to early endosomes (marked as Rab5WT and Rab5CA) (Figure 27 A-D). Similar to the WT, E268Q CIC-5 was present on endosomes, in an ER-like structure and in the PM.

The colocalization analysis showed that approximately 30% of identified CIC-5 objects colocalized with both, Rab5WT and Rab5CA as well as 50% of Rab5WT or Rab5CA objects overlapped with CIC-5. Furthermore, the identified objects were a lot alike as the size based colocalization showed that at least 50% of the total size of objects was overlapping (Figure 28 B, D).

In conclusion, the E268Q mutant did not altered the subcellular distribution of CIC-5. Like WT CIC-5, it was located to the ER, the PM, and showed a distinct colocalization to early endosomes, marked with Rab5WT and Rab5CA in HT-29 cells.

Figure 28: Colocalization of the non-transporting mutant E268Q CIC-5 with Rab5WT and Rab5CA.

A), B) C), E) Single z-slices of representative confocal images showing the localization of E268Q CIC-5-EYFP (in green) together with either Rab5WT-RFP (**C**) or Rab5CA-mCherry (**E**) (both Rab5s in red) in HT-29 cells. **D, E and F)** Box plots summarizing the results from object-based and size-based colocalization analysis. Objects in the two fluorescence channels were identified and the colocalization coefficients were calculated. The fluorescence channels were defined as Rab5WT or Rab5CA and CIC-5. N=7 cells for Rab5WT and n=4 cells for Rab5CA were analyzed. Single cells (•), 25 – 75 % (□, large box), mean (◇), median (—) as well as 99 % and 1 % (X). Scale bars correspond to 10 μ m. (modified from Ruhe et al., 2017)

3.1.5 TcdA colocalizes with CIC-5

C. difficile's toxins TcdA and TcdB enter the host cell via clathrin-dependent and independent endocytosis pathways (Gerhard et al., 2013; Papatheodorou et al., 2010). Therefore, the toxins have to use the hosts' endocytotic machinery to gain access into the cell. After being internalized, the toxin is located in endosomes, and since CIC-5 is situated on early and late endosomes, it was expected that TcdA and CIC-5 colocalize to some extent. First, to investigate the internalization of EGFP-tagged TcdA in HT-29 cells transiently overexpressing CIC-5, cells were incubated with the toxin and the fluorescence of EGFP-TcdA and CIC-5-mCherry was visualized under a confocal microscope (Figure 29 A). The toxin was bound to the surface membrane and also located in intracellular vesicles. To analyze the amount of colocalizing CIC-5 and TcdA objects, a colocalization analysis was performed. Around 30% of TcdA objects colocalized with CIC-5 objects, with an overlapping area of approx. 40% of the total area of TcdA objects (Figure 29 A and B). Less CIC-5 objects colocalized with TcdA objects (around 15%) and the area of overlapping objects was also smaller (also approx. 15%) than compared to TcdA objects. Nevertheless, this indicated a distinct colocalization of TcdA and CIC-5. Yet, the major amount of toxin was restricted to the cell membrane and only little was internalized in CIC-5 expressing cells (Figure 29 A).

Figure 29: Internalization of TcdA-EGFP and colocalization with CIC-5 in living cells (modified from Ruhe et al., 2017).

A) Representative dual color confocal image showing the localization of TcdA-EGFP and CIC-5-mCherry in HT-29 cells. Cells transiently expressing mCherry-tagged CIC-5 (red) were incubated with TcdA-EGFP (green). **B)** Box plot summarizing the results from an object- (left) and size-based (right) colocalization analysis of images as depicted in **(A)**. Objects in the two fluorescence channels were identified and the colocalization coefficients were calculated. The two channels were defined as CIC-5- and TcdA-containing objects. N=6. Single cells (•), mean (◇), and median (—). Scale bars correspond to 10 μm. Cell culture and microscopy was performed by R. Abromeit, image processing and colocalization analysis was done by F. Ruhe.

In order to examine the kinetics of intoxication, HT-29 cells transiently expressing CIC-5 mCherry were intoxicated with EGFP-tagged TcdA at 37°C and internalization was stopped by fixation of the cells after 0, 8 or 15 minutes (Figure 30). Independent of the time of internalization at 37°C, the images showed nearly no TcdA intracellularly. Most of the toxin was bound to the PM, whereas CIC-5 was situated inside the cell. The colocalization analysis of CIC-5- and TcdA- objects was also performed and showed a weak colocalization (Figure 30 C). The object based colocalization analysis also showed a very small amount of colocalizing objects in all three time steps. Only at the 8 min internalization step, the area of overlapping pixels from the few detected overlapping objects was slightly higher than at the other timer intervals. Because live cell images proofed that the toxin was endocytosed in HT-29 cells (see Figure 29 A), the lack of intracellularly detected TcdA might be a result of the fixation procedure.

Figure 30: Localization of TcdA-EGFP and CIC-5 in fixed HT-29 cells (modified from Ruhe et al., 2017).

A), B) Representative confocal images of fixed HT-29 cells transiently transfected with CIC-5-mCherry (red) and intoxicated with TcdA-EGFP (green). Cells were fixed immediately upon toxin incubation (**A**) or after 15 min incubation at 37°C (**B**). **C)** Box plot summarizing the results from an object- (left) and size based (right) colocalization analysis. Objects were detected in the two fluorescence channels and the colocalization coefficient of overlapping objects (object based) or the area of overlapping objects (size based) colocalization was calculated. The channels were defined as CIC-5 and TcdA. N=8 cells for 0 and 8 min and n=10 cells for 15 min of toxin internalization. Single cells (•), mean (◇) Scale bars correspond to 10 µm.

These findings raised the question if the small amount of internalized TcdA that was detected in living cells was also a result of a destructed EGFP-fluorescence. As a control and in order to circumvent the problem of destructed or quenched EGFP-tagged TcdA, untagged toxin was used and labeled with an Atto425 NHS-ester dye to fluorescently label TcdA and visualized in HT-29 as well as HEK293T cells (see Figure 31). In this case, cells were not fixed but living cells were used for confocal imaging. It is worth noticing, that compared to the EGFP-tagged TcdA that was internalized in living cells (see Figure 29), Atto425-labeled TcdA resulted in a more diffuse intracellular localization, especially in HT-29 cells. Additionally, the toxin was less membrane-bound. The colocalization analysis of CIC-5 objects and objects of the labeled toxin showed a smaller object and size based colocalization coefficient (under 10% in HT-29 and HEK293 cells) (Figure 31 C and D) than the EGFP-tagged toxin (around 30% of TcdA objects colocalized with CIC-5 objects in HT-29 cells, and 10% of CIC-5 with TcdA objects) (Figure 29 C).

In conclusion, the fixation of cells intoxicated with EGFP-TcdA resulted in the loss of the fluorescence intensity of intracellular toxin. Labeling TcdA with the Atto425 NHS-dye caused a diffuse subcellular localization of the toxin. This leads to the assumption that the initial attempt, to measure the colocalization of EGFP-TcdA and CIC-5-mCherry in living cells was the best approach to determine the colocalization coefficient of both proteins. This approach showed a distinct colocalization of toxin and antiporter.

Figure 31: Localization of CIC-5 and labelled TcdA

A), B) Representative dual color confocal images of living HEK293T (**A**) and HT-29 (**B**) cells transfected with CIC-5 YFP (red) with internalized Atto425-labeled TcdA (green). A 45 min (HEK293T) or 70 min (HT-29) incubation with Atto425-TcdA on ice was followed by 5 min incubation step at 37°C. **C and D)** Box plot summarizing the results from an object (left) and size based (right) colocalization analysis. 4 cells for each cell line were analyzed. Single cells (•), mean (◊), and median (-). The two channels were defined as CIC-5 and TcdA containing objects. Scale bars correspond to 10 µm.

3.1.6 Internalization of TcdA in WT or E268Q CIC-5 cells

The increased susceptibility of CIC-5 expressing cells towards TcdA and TcdB might be a result of a higher amount of toxin internalized in these cells. In order to investigate the amount of endocytosed and membrane bound TcdA, HEK293 cells stably expressing WT or E268Q CIC-5-mCherry, or mCherry alone (as a control) were intoxicated with Atto425 labeled TcdA. Stably transfected HEK293 cells were used, because the attempt to create stably transfected HT-29 was not successful and for this approach, it was necessary that all cells were overexpressing one of the CIC-5 variants or mCherry. The fluorescence of the labeled toxin was then measured and normalized to the amount of cells in the sample (the calibration curve for the absorbance is depicted in Figure 19). The fluorescence spectrum as well as the fluorescence intensity at 490 nm (Figure 32, inset) showed that there was significantly more toxin internalized in cells expressing WT or E268Q CIC-5. Yet, the amount of TcdA was twice as much in WT CIC-5 cells than in the non-transporting mutant E268Q.

Figure 32: WT or E268Q CIC-5 increase endocytosis of TcdA (modified from Ruhe et al., 2017).

The fluorescence intensity of TcdA per cell is shown. HEK293 cells stably expressing mCherry (blue), CIC-5-mCherry (WT, black), or E268Q CIC-5-mCherry (red) were intoxicated with 200 nM TcdA, labeled with Atto425. N=9 petri dishes for WT and E268Q CIC-5-mCherry and n=10 petri dishes for mCherry on two different days. Inset represents a box plot of normalized fluorescence intensity (FI) at 490 nm emission. Single cells (•), mean (■), and median (-). *indicates a significant difference between two data sets. The significance was tested using a two-tailed t-tests and significance was set at a P value of <0.05.

3.1.7 WT and E268Q CIC-5 promote endosomal acidification

In addition to a higher amount of internalized toxin, it is also possible that the toxin is processed faster due to a lower pH in CIC-5 expressing cells. In order to test this theory, vesicular pH measurement in WT and E268Q CIC-5 overexpressing cells were performed. Consequently, HEK293T cells were transiently co-transfected with either WT CIC-5-mCherry or E268Q CIC-5-mCherry together with the pH-sensitive fluorescence protein synapto-pHluorin2 (Mahon, 2011, Südhof, 1995).

The (co-) localization of synapto-pHluorin2 and CIC-5 is depicted in Figure 17 A. Based on the measured ratios and the calibration curve (see Figure 17) the actual pH of cells expressing WT or E268Q CIC-5, or the control (synapto-pHluorin2 alone) was calculated (Figure 33). WT and E268Q CIC-5 showed a similar pH, which was significantly lower than in control cells.

Figure 33: CIC-5 promotes acidification (modified from Ruhe et al., 2017).

Analysis of vesicular pH of HEK293T cells transiently co-expressing WT or E268Q CIC-5-mCherry and synapto-pHluorin2 or solely expressing synapto-pHluorin2 (control). N=46 cells for WT CIC-5, n=44 cells for E268Q CIC-5 and n=34 cells for the control. The results shown are means ± SEM. * indicates a significant difference between the control and the sample. The significance was tested using a student's t-test and significance was set at a $p < 0.05$.

In summary, the investigations on the role of CIC-5 for TcdA intoxication showed that CIC-5 promotes intoxication by TcdA by an increased endocytosis of toxin. In addition, the more acidic pH in CIC-5 positive endosomes might further accelerate toxin processing, thus increasing its toxicity.

3.2 Tool to study endosomal motility with regard to the pathophysiology of Dent's disease

Endocytosis is a crucial cellular process to maintain homeostasis for instance of membrane bound proteins (as reviewed in Maxfield and McGraw, 2004), but it also presents an entrance for pathogens to invade the host cell. In the previous chapter, it was demonstrated that CIC-5 plays an important role in the intoxication of toxins from *C. difficile*. However, not only endocytosed toxins can cause diseases, but also a malfunctioning endocytosis pathway caused by mutations in the *CLCN-5* gene can lead the kidney related Dent's disease (Wrong et al., 1994). CIC-5 positive endosomes are highly motile vesicles. Multiple Dent's disease causing mutations of CIC-5 are retained in the ER and show a disrupted electrochemical behavior with reduced or aborted exchange of protons and chloride (Smith et al., 2009). Additionally, many of these mutations have an impaired glycosylation pattern which led to the hypothesis that endosomal trafficking might be influenced by the glycosylation status of CIC-5. Therefore, the second part of this study focused on the trafficking and motility of CIC-5 endosomes. In order to understand the role of glycosylation in this process, the Dent's disease causing CIC-5 mutant R516W was used and two artificial glycosylation deficient mutants were generated (N408E and N408A). In a next step, the particle movement was analyzed by TIRF microscopy followed by particle tracking and data analysis, and finally the endosomal pH and the endocytosis rate were measured.

3.2.1 Generation of N-glycosylation deficient CIC-5 mutants

Glycosylation is a crucial posttranslational modification that is involved in intercellular communication, adhesion, and migration (Bard and Chia, 2016). It occurs in the ER and Golgi and is characterized by the attachment of branched sugar polymers. In *Xenopus laevis*, CIC-5 was shown to be N-glycosylated. In general, there are two types of glycosylation: Core and complex. The core glycosylation is composed of glycans that are attached to the protein in the ER. Upon further trafficking into the Golgi, these glycans are modified, completing the complex glycosylation (Lodish et al., 2000). Glycosylation has been shown to be crucial for the transport of CIC-5 to the PM (Schmieder et al., 2007). Multiple Dent's disease mutations result in proteins that have no complex glycosylation and are retained in the ER (Smith et al., 2009).

Using the NetNGlyc 1.0 Server (Blom et al., 2004) to predict possible N-glycosylation sites based on the glycosylation motif Asn-X-Ser/Thr, two possible N-glycosylation sites at asparagine (Asn) 38 and 408 (Figure 34) were revealed. Since the Asn at position 408 has been already reported to be important in *Xenopus laevis* for the glycosylation of CIC-5 (Schmieder et al., 2007), the glycosylation-deficient CIC-5 variants were generated introducing a mutation at this particular position.

Using the Quick-Change mutagenesis, the asparagine (N) was replaced by a nonpolar alanine (A) or a polar glutamine (E) resulting in the two distinct CIC-5 mutants: N408A and N408E.

Figure 34: Possible N-glycosylation sites in the human CIC-5 protein predicted by the NetNGlyc 1.0 Server(Blom et al., 2004).

The server predicts N-glycosylation sites based on the motif Asn-X-Ser/Thr. Two possible positions were detected at the amino acids 38 and 408. The Asn (N) is marked in red and the rest of the motif in blue.

3.2.2 The mutants R516W, N408E, and N408A CIC-5 are not complex glycosylated

As mentioned before, the WT CIC-5 protein has been described to be complex glycosylated (Schmieder et al., 2007). In general, during the maturation of the protein, unmodified glycans (high-mannose N-glycans) are attached to the protein in the ER and complex N-glycans are a result of further processing in the Golgi. Therefore, the glycosylation status might indicate if the protein is trafficked correctly (Freeze and Kranz, 2010; Magnelli et al., 2011). Using the endoglycosidases Endo H and PNGase F, glycosylation of the different CIC-5 constructs was examined. Endo H cannot cleave N-linked complex-glycan whereas PNGase F can cleave complex, high-mannose residues. Therefore, protein lysates from HEK293T cells transiently transfected with WT, R516W, N408E, or N408A CIC-5-mCherry were digested with Endo H and PNGase F, respectively (Figure 35). In the untreated WT CIC-5 sample, two bands between 90-120 kDa were visible.

Only PNGase F was able to cleave the modified glycans, indicating that WT CIC-5 was complex glycosylated. Densitometric analysis shows that the R516W was only core- and/or non-glycosylated (see Supplemental Figure 1). The newly-created N408E and N408A mutants proved both to be glycosylation deficient. Densitometric measurement showed only one band with the size of around 90 kDA, representing the core- and/or non-glycosylated protein (see Supplemental Figure 1).

In general, this indicated that the WT CIC-5 was complex glycosylated, the R516W was core- and/or non-glycosylated and the N408E and N408A mutants showed no glycosylation.

Figure 35: Endo H and PNGase F assay of WT, R516W, N408E and N408A CIC-5-mCherry.

To estimate the glycosylation status of the different CIC-5 variants, whole protein lysates of HEK293T cells transiently transfected with WT, R516W, N408E or N408A CIC-5-mCherry were used. The protein samples were thus subjected to digestion with the endoglycosydases Endo H or PNGase F. Endo H cannot cleave N-linked complex-glycan, whereas PNGase is able to cut of these complex glycans. + indicates the size of the complex glycosylated protein and * the core- and/or non-glycosylated protein size. The profile plots of each lane are shown in Supplemental Figure 1.

3.2.3 Cellular distribution of WT and mutant CIC-5 in MDCKII cells

According to the altered glycosylation status, the subcellular localization of WT, R516W, N408E and N408A CIC-5-mCherry in MDCKII cells was investigated in the next approach (Figure 36). WT CIC-5 appeared as punctuated, intracellular structures and to a small extent to the PM. The R516W mutant was mainly located to an ER-like structure and to a smaller amount in vesicles. The two glycosylation deficient mutants N408E and N408A were also located to endosomes as well as in an ER-like structure but less to the PM as the WT. This indicates that the subcellular distribution of CIC-5 is not dependent on its glycosylation pattern.

Figure 36: Subcellular distribution of WT, and mutant CIC-5-mCherry in MDCKII cells.

Representative confocal images of WT (A), R516W (B), N408E (C) and N408A (D) CIC-5 mCherry transiently expressed in MDCKII cells. Single z-slides are depicted. The scale bar represents 10 μm .

3.2.4 Particle Tracking of CIC-5 endosomes

Since confocal images display only the steady state distribution of CIC-5, the question raised if the kinetics of endosomal trafficking were affected by glycosylation-deficient mutants. In order to characterize the motility of CIC-5 positive endosomes, time-lapse imaging using a TIRF microscope were performed. Either a cycle time of one second (low temporal resolution) or 302 milliseconds (high temporal resolution) was used. Endosomes were identified and their movement was tracked. The lifetime, mean velocity, net displacement, and mean square displacement (MSD) were analyzed. An endosome that was detected in one frame was defined as a particle and if it occurred in more than three consecutive frames, it was referred to as a trajectory (Figure 37 and Figure 38). The lifetime described how long the endosome was detected and therefore visible in the movie. The displacement from its origin was defined as net displacement. The software was able to correctly detect and link particles (see Figure 37 left images). However, not all endosomes were detected because very fast particles or particles occurring for a very short time were not tracked by the program. In order to investigate if CIC-5 positive endosomes moved exclusively along microtubules, nocodazole was added to disrupt the microtubule network (Figure 37 A). In the nocodazole control experiment, only a few long trajectories and mainly short-living particles were visible. Whereas in the movies of the different CIC-5 constructs, multiple long as well as very short trajectories were detected. This showed that CIC-5 positive endosomes were indeed moving along microtubules and were not freely diffusing through the cell. The trajectories of the different CIC-5 constructs suggested that WT CIC-5 endosomes were moving more organized and less in a zick-zack mode than the mutants, indicating that the motility might have been altered in all three mutants (Figure 37 A-F).

Figure 37: The tracking software, u.track2.1.3 (Jaqaman et al., 2008), tracks CIC-5 positive endosomes accurately.

The result of the particle tracking of WT, R516W, N408E, and N408A CIC-5 positive endosomes is depicted (A-E, left images) and the first frame of the correlated movies (A-E right image). Nocodazole is shown as control for the motility without microtubule (A). WT CIC-5 is shown in (B), R516W in (C), N408E in (D) as well as N408A in (E). Endosomes were recorded using a TIRF microscope with a field depth of 95 nm and a cycle time of one second. Scale bars represent 10 μm.

Figure 38: Time lapse images of CIC-5 trajectories.

Detailed example of the movement of WT CIC-5 positive endosomes and their trajectories in the low temporal resolution. The time lapse represents the trajectories from the white square of the bigger image with one frame every 5 seconds. The colored lines represent the detected trajectories of the specific endosome.

3.3 Low and high temporal resolution

First it was unknown whether differences in long living, slow endosomes or fast moving, short living endosomes exist. Therefore, two cycle times were used and examined in terms of lifetime, net displacement, mean velocity, and MSD. First, the results of the low and then of the high temporal resolution will be displayed. An overview of the amount of measured cells and detected particles/trajectories is given below in Table 2.

In the following paragraphs, the analyzed parameters were evaluated in a 1D to 2D and finally a 3D analysis approach. The aim was to identify not only differences between the CIC-5 constructs, but also correlations between the different parameters. In the 1D analysis, mean values of trajectories from single cells were extracted and evaluated. In the 2D approach two parameters were compared with each other. In the 3D analysis, mean values of three factors of each single cell were analyzed.

Table 2: Overview of the amount of analyzed cells, detected particles and linked trajectories of CIC-5 positive endosomes from MDCKII cells.

CIC-5 construct	low temporal resolution			high temporal resolution		
	cells	particles	trajectories	cells	particles	trajectories
WT	22	90755	34138	14	64234	27320
R516W	19	61705	15850	13	74898	14192
N408E	22	143352	55048	15	74910	37106
N408A	20	69256	25127	19	80071	29068

3.4 Low temporal resolution of particle tracking

For the low temporal resolution, movies of one second cycle time with 300 frames were recorded. The low temporal resolution enabled the tracking of slower moving endosomes for a longer time without the problem of losing signal due to bleaching.

3.4.1 WT CIC-5 has the longest lifetime with the slowest mean velocity in the low temporal resolution

In the 1D analysis approach, single parameters of all trajectories as means of single cells were compared between the different CIC-5 variants. Each cell had different amounts of endosomes. Since single cells within the population of one CIC-5 construct may have a greater influence on the calculated parameters if there were more endosomes detected in these cells than in the other cells, mean values of single cells were calculated. However, pooling all trajectories from all cells expressing one CIC-5 variants showed similar results to mean values of single cells (Supplemental Figure 2).

In a first step, the correlations between the different parameters were investigated. Thus, the mean values of the lifetime, net displacement and mean velocity of single cells were examined (Figure 39 for means of cells). Here, the two glycosylation deficient mutants (N408E and N408A) had a significantly shorter lifetime compared to the WT (Figure 39 A). The net displacements were not statistically different, except for the R516W which traveled a smaller distance than the N408E (Figure 39 B). With regard to the mean velocities, significant differences were found between most constructs: WT and R516W were the slowest and the glycosylation deficient mutants the fastest (Figure 39 C).

Figure 39 Lifetime, net displacement and mean velocity of trajectories from single cells recorded with the low temporal resolution.

Box plots of mean values of the lifetime (A), net displacement (B), and mean velocity (C) of all trajectories from single cells recorded with the low temporal resolution are depicted. Single cells (•), mean (■), median (-). * indicates a significant difference between two values. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05. N=22 cells for WT and N408E, n=19 cells for R516W, and n=20 cells for N408A.

In order to examine possible correlations between the parameters, the mean values of all endosomes from single cells were analyzed in terms of lifetime versus net displacement and the net displacement was also plotted against the velocity (Figure 40). In general, plotting lifetime versus velocity (Figure 40 A), indicated that the faster the vesicles were moving, the shorter was their lifetime. Another correlation between the mean velocity and net displacement became visible: The faster particles were moving, the more distance was covered from their origin. However, a longer lifetime did not necessarily result in a higher net displacement (Figure 40 B). All four CIC-5 constructs showed similar correlations and only the cells expressing WT CIC-5 formed a small group of slowly yet far moving endosomes (see Figure 40 C)

Figure 40: Correlations of lifetime, net displacement and mean velocities of trajectories recorded at the low temporal resolution.

Mean values of endosomes from WT CIC-5 are depicted in blue, R516W in green, N408E in cyan and N408A in red. Mean values of all trajectories of one cell (each cell is represented by one dot) of the different CIC-5 variants are shown. The 2D analysis is shown in A, B and C and the 3D in D. Lifetime versus velocity is depicted in A), lifetime versus net displacement in B) net displacement versus velocity in C). Mean \pm SEM are shown in A, B and C and in D, only mean values are depicted. N=22 cells for WT and N408E, n=19 cells for R516W, and n=20 cells for N408A.

In order to further visualize the differences between the populations of cells expressing the same CIC-5 construct, a 3D plot of net displacement versus lifetime versus mean velocity was constructed (Figure 40 D). The WT formed a denser group, with only one cell that had a very short lifetime and net displacement.

Cells of the R516W mutant were broadly distributed, such as the N408E and N408A mutant. Overall, there was a major overlap of all cells of all four CIC-5 variants.

In general, in the low temporal resolution, the WT and R516W displayed the highest lifetime; net displacements were very similar between all four CIC-5 constructs; only the R516W had a significantly lower net displacement as compared to the N408E mutant. It is noteworthy that the mean velocities differed considerably between most CIC-5 variants: The WT had the slowest and the N408E the fastest mean velocity.

3.4.2 Calculation of Mean Square Displacement

The most common way to describe particle movements is by using the mean square displacement (MSD), which is a value for the mean square distance traveled by a particle along the x-y axis (in μm^2) in a specific time interval/lag Δt (examples for MSD curves can be seen in Figure 41). In detail, it is evaluated how far a particle is moving for a certain time lag over its whole trajectory's lifetime. For instance, for a time lag of one second, the distance travelled every second from the trajectory's origin until its end is examined and a mean value is calculated. The same is then done with a time lag of two seconds, where the distance travelled every two seconds is calculated. Here, not the displacement from the origin, which was defined as net displacement in this study, was considered, but the total distance travelled by the endosome was used (a detailed description is depicted in Figure 15).

MSD analysis can also be used to describe the motility of particles. Here, the curve progression is examined in order to distinguish between free diffusion, active transport or anomalous behavior (Figure 16). MSD curves from single trajectories and the mean MSD curve of all trajectories of single cells of the different CIC-5 constructs indicated that the endosomal movement can be described as anomalous (Figure 41): no limit was reached but the progression curve decreased at longer time lags.

Figure 41: Single and mean MSD curves of trajectories of WT, R516W, N408E and N408A CIC-5 in the low temporal resolution.

The MSD curves of all trajectories from WT, R516W, N408E and N408A CIC-5 were calculated and visualized using TrackArt (Matysik and Kraut, 2014). MSDs of single cells are depicted as black lines, mean values from all cells in colored lines. N=22 cells for WT and N408E, n=19 cells for R516W, and n=20 cells for N408A.

Based on the calculated MSD, the diffusion coefficient D (also named transport coefficient) was calculated indicating the squared distance traveled per second (in $\mu\text{m}^2/\text{s}$). The diffusion coefficient of the WT and R516W CIC-5 were smaller as compared to the N408E and N408A mutants. However, the test for significance assessed only the WT to have significantly lower D values than the N408E (Figure 42).

Figure 42: Diffusion coefficient (D) of trajectories as means of single cells.

The D coefficients of trajectories of the WT CIC-5 (blue), or of the CIC-5 mutants R516W (green), N408E (cyan) or N408A (red) were calculated using TrackArt (Matysik and Kraut, 2014). Mean values of all trajectories of single cells are depicted, each dot represents one cell. Single cells (\bullet), mean (\blacksquare), and median ($-$). * indicates a significant difference between two values. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05 . N=22 cells for WT and N408E, n=19 cells for R516W, and n=20 cells for N408A.

In conclusion: The motility of endosomes from all CIC-5 constructs showed kinetics described by anomalous diffusion; the analysis of the transport coefficient indicated the significantly faster diffusion of the N408E mutant as compared to the WT.

3.5 High temporal resolution of particle tracking

For the high temporal resolution, time-lapse images with the shortest possible cycle time for the utilized TIRF microscope were recorded with a 302 ms frame rate for 500 frames. The faster frame rate enabled the tracking of faster moving endosomes which might be lost using a slower frame rate.

3.5.1 Endosomes of the R516W CIC-5 have a shorter lifetime and faster mean velocity as compared to the WT

Comparing the mean values of lifetime, net displacement and mean velocity of single cells recorded with a faster cycle time showed a similar behavior of WT and N408E (see Figure 43 for mean of cells and Supplemental Figure 4 for all trajectories from all cells). The N408A had the longest and the R516W the shortest lifetime. The net displacements were also significantly different between most of the constructs: The WT and the N408E had endosomes that moved the furthest from their origin, whereas R516W and N408A endosomes moved significantly shorter distances from their origin as compared to WT and N408E. The mean velocity showed significantly different values between most CIC-5 variants, except the WT and N408E mutant. Here, the R516W had the fastest endosomes, followed by the WT and N408E, whereas the N408A mutant had the slowest endosomes.

In comparison with the low temporal resolution, the high temporal resolution was able to detect more significant differences between the WT and the CIC-5 mutants (see Figure 39 and Figure 43) but the distribution of the lifetime, net displacement and mean velocity were different between both cycle times. The R516W for instance had the longest lifetime in the low and the shortest in the high temporal resolution. The net displacement was very similar in all CIC-5 variants in the low temporal resolution but the high temporal resolution was able to detect differences. The mean velocities were also quite different between low and high temporal resolution, for instance the R516W had the fastest endosomes in the high and one of the slowest in the low temporal resolution.

Figure 43: Lifetime, net displacement and velocity of all trajectories from single cells of the high temporal resolution.

Box plot of mean values of all trajectories from single cells recorded at the high temporal resolution are shown. Single cells (•), mean (■), and mean (-). * indicates a significant difference of $p < 0.05$ between two values. Significance was tested using the One-way Anova with post-hoc Tukey HSD. N=14 cells for WT, n=13 cells for R516W, n=15 cells for N408E, and n=19 cells for N408A.

The 2D graphs of lifetime versus mean velocity, lifetime versus net displacement and net displacement versus mean velocity showed the same correlation as in the low temporal resolution (Figure 44): The faster endosomes were moving, the shorter was the lifetime and the more distance was covered by the trajectory. Plotting the mean values of the lifetime versus net displacement versus mean velocity of all trajectories of each cell in a 3D graph showed that each CIC-5 construct formed a cloud of cells. The cells expressing the WT and N408E had a greater variety in their endosomal movement, forming a less dense cloud than the R516W or N408A (Figure 44 D).

Figure 44: 2D and 3D plots of trajectories as means from single cells of the high temporal resolution.

WT CIC-5 is depicted in blue, R516W in green, N408E in cyan and N408A in red. Mean values of all trajectories of one cell (each cell is represented by one dot) of the different CIC-5 variants are depicted. The 2D analysis is shown in **A**, **B** and **C** and the 3D in **D**. Lifetime versus velocity is depicted in **A**), lifetime versus net displacement in **B**) net displacement versus velocity in **C**). Mean $\pm\text{SEM}$ are shown in A, B and C. Only mean values are depicted in D. N=14 cells for WT, n=13 cells for R516W, n=15 cells for N408E, and n=19 cells for N408A.

In general, in the high temporal resolution, the WT showed slow moving endosomes that were recorded for a longer time and also moved over a longer distance from their origin. The R516W had endosomes that were detected for a short time but moved the fastest for a short distance (Figure 43 and Figure 44). Importantly, although the N408A mutant had endosomes that moved close to the PM for a long time (indicated by their long lifetime) they were the slowest endosomes moving the shortest distance from their origin.

3.5.2 Calculation of Mean Square Displacement (MSD)

MSD analysis of single cells and mean of single cells from the different CIC-5 variants showed again an anomalous curve progression (Figure 45). The N408E had the greatest variance in the MSD curves of single cells (Figure 45 C) as compared to the WT and the R516W and N408A mutant.

Figure 45: Single and mean MSD curves of trajectories of WT, R516W, N408E and N408A CIC-5 in the high temporal resolution..

The MSD of all trajectories from single cells transiently transfected with WT, R516W, N408E and N408A CIC-5 mCherry were calculated and visualized using TrackArt (Matysik and Kraut, 2014). MSDs from single cells are depicted as black lines and mean values \pm SEM from all cells of the specific CIC-5 construct are depicted as colored lines. N=14 cells for WT, n=13 cells for R516W, n=15 cells for N408E, and n=19 cells for N408A.

In order to get a better understanding of the MSDs of different trajectories within one cell, 50 trajectories from each CIC-5 construct were chosen by chance and their MSD curves were analyzed (see Figure 46). The 50 MSD curves were also binned together and fitted using a linear fit. Although, at the first glance, the MSD progression curves with the linear fit seemed quite different, they all showed an anomalous behavior (Figure 46 lower row). This supports the anomalous diffusion of the previous MSD analysis of all cells and it also indicates the great variance in MSD curves within the trajectories of one cell.

Figure 46: Overview of 50 single MSD curves and the fitted average MSD of CIC-5 endosomes.

50 trajectories from one representative cell were randomly picked and the single MSD curves of WT, R516W, N408E or N408A mutant CIC-5 were calculated (**upper row**). Then all MSDs of all 50 trajectories were fitted using a linear fit (**lower row**).

Based on the MSDs the diffusion coefficients D were also extracted (Figure 47). The N408A mutant had the lowest D values followed by the R516W and the WT. The N408E had the, overall, highest D value but also a very broad distribution within its population. The WT had a significantly higher D value than the N408A, and the N408A had a higher value than the R516W and N408E.

Figure 47: Diffusion coefficients (D) of all trajectories from CIC-5 endosomes in single cells.

D values of trajectories of the WT (blue), R516E (green), N408E (cyan) or N408A CIC-5-mCherry (red) were calculated using TrackArt (Matysik and Kraut, 2014). Mean values of all trajectories of single cells are depicted. Single cells (\bullet), mean (\blacksquare), and median ($-$). $N=14$ cells for WT, $n=13$ cells for R516W, $n=15$ cells for N408E, and $n=19$ cells for N408A. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05 .

3.5.3 WT and N408E CIC-5 endosomes move more target-oriented than R516W and N408A CIC-5 endosomes

The tracked endosomes seemed to be walking more directionally in the WT than in the mutants (Figure 37). In order to investigate if the mutant and WT CIC-5 endosomes were moving linearly or rather in an unorganized fashion, the target-orientation of the endosomal walk was calculated. The target-orientation was defined as the net displacement divided by the total distance walked by a trajectory. The higher the value, the more efficient is the target-oriented movement of endosomes. Mean values of all trajectories from single cells were again calculated and are illustrated in Figure 48.

Figure 48: Target-orientation of endosomes from WT, R516W, N408E, and N408A CIC-5 endosomes.

Mean values of all trajectories of single cells are depicted. In a Box plot. Single cells (*), mean (■), and median (-). N=14 cells for WT, n=13 cells for R516W, n=15 cells for N408E, and n=19 cells for N408A. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05.

The WT had a target-orientation of 0.36 ± 0.01 (SEM), the R516W 0.32 ± 0.008 , N408E 0.37 ± 0.01 , and N408A 0.32 ± 0.006 . It is worth noticing that the cells of the N408A CIC-5 variant had very similar efficiency values, whereas the WT and N408E showed greater variances in the cells population. In general, endosomes of the WT and N408E CIC-5 walked with a significantly more target-orientation away from their origin than the R516W and N408A CIC-5 endosomes.

3.5.4 Comparison of low and high temporal resolution

In this study, two different frame rates were used and the movies were recorded over different time periods. The high temporal resolution had a frame rate that was 3.3 times faster than in the low temporal resolution (a cycle time of one second or 302 milliseconds were used). Furthermore, movies were recorded for half the time in the high compared to the low temporal resolution (151 s and 300 s). As mentioned before, the shorter frame rate proofed to be able to detect faster endosomes that were lost in movies recorded in the slower frame rate. Astonishingly, the distribution of lifetime, net displacement, mean velocity, and MSD were quite different between both frame rates (Table 3). The WT, for instance, had the longest lifetime in the low temporal resolution, whereas the N408A showed the longest lifetime in the high temporal resolution.

Table 3: Comparison of the lifetime, net displacement, mean velocity, and D values between the low and high temporal resolution.

	Lifetime (s)		Net displacement (μm)		Mean velocity ($\mu\text{m/s}$)		D ($\mu\text{m}^2/\text{s}$)	
	Low	High	Low	High	Low	High	Low	High
WT	33.7 ± 0.23	14.5 ± 0.13	0.79 ± 0.004	0.84 ± 0.006	0.13 $\pm 3.1\text{E-}4$	0.36 ± 0.001	0.005 $\pm 2.2\text{E-}4$	0.015 ± 0.0013
R516W	30.8 ± 0.31	10.5 ± 0.14	0.76 ± 0.005	0.68 ± 0.006	0.14 $\pm 4.2\text{E-}4$	0.42 ± 0.001	0.0052 $\pm 4.9\text{E-}4$	0.013 ± 0.0012
N408E	25.9 ± 0.13	13 ± 0.1	0.85 ± 0.003	0.82 ± 0.004	0.15 $\pm 2.5\text{E-}4$	0.38 ± 0.001	0.0065 $\pm 4.3\text{E-}4$	0.018 ± 0.002
N408A	27.9 ± 0.22	15.6 ± 0.13	0.8 ± 0.004	0.63 ± 0.004	0.15 $\pm 3.6\text{E-}4$	0.3 $\pm 9.6\text{E-}4$	0.0058 $\pm 5.0\text{E-}4$	0.009 $\pm 9.2\text{E-}4$

In theory, endosome that were detected in the low temporal resolution would have been detected in the high temporal resolution, but not vice versa as very fast endosomes or those with a short lifetime were lost in the low resolution. However, visual comparison of the movies with the tracked trajectories made it obvious, that very fast endosomes, or endosomes appearing only for a very short time, were not tracked even in the high temporal resolution. Furthermore, if an endosome moved too far between frames, it was not recognized as the same trajectory.

This raises the question as to the experimental limitations and the thresholds for the lifetime, velocity and displacement. For the lifetime, the threshold was three seconds for the low and 906 milliseconds for the high temporal resolution, as only trajectories with more than three frames were analyzed. In order to determine a threshold for the displacement and velocity, the values of the endosomal movement from frame to frame were analyzed (the velocity and displacement of particles are depicted in Supplemental Figure 4) and the fastest particles/endosomes of each CIC-5 construct were extracted. In the low temporal resolution, the fastest detected endosomes in all four CIC-5 constructs had a velocity of 1.3 $\mu\text{m/s}$ from frame to frame. In the high temporal resolution, the highest speed was 4.4 $\mu\text{m/s}$. The greatest detected distance travelled from one frame to the other was 1.3 μm in both cycle times. Based on these values, one can conclude that for the low temporal resolution, endosomes that moved faster than 1.3 $\mu\text{m/s}$ from frame to frame were not detected and for the high temporal resolution, all endosomes faster than 4.4 $\mu\text{m/s}$ were not detected or lost. Since the highest detected displacement was the same in the low and high temporal resolution, the maximum step that an endosome could go and still be recognized as one trajectory was 1.3 μm .

In conclusion, the high temporal resolution was able to detect more differences in terms of lifetime, mean velocity and MSD between the four CIC-5 variants. Due to its ability to detect faster endosomes and because of the fact that the endosomal speed was obviously altered in the CIC-5 Dent's and glycosylation deficient mutants, the results of the high temporal resolution are most likely to be more profound than the results of the low temporal resolution. Based on these findings, the particle tracking revealed that the R516W had the lowest lifetime and the fastest endosomes. The N408A presented the longest lifetime and slowest velocity.

3.5.5 All CIC-5 variants promote endosomal acidification

The next step aimed at evaluating reasons for the altered endosomal motility. It is established that the accumulation of protons in endosomes regulates their maturation from early to late and recycling endosomes (Sorkin and von Zastrow, 2002). Thus, it is possible, that endosomes of the CIC-5 mutants matured faster or slower than the WT. The different motilities of WT, R516W, N408E and N408A CIC-5 might have been caused by an altered acidification of endosomes. In order to examine if the endosomal pH of the WT and mutant CIC-5 was different, HEK293T cells transiently expressing WT, R516W, N408E, or N408A CIC-5-mCherry and cotransfected with synapto-pHluorin2 (Mahon, 2011) and subjected to confocal imaging. For a more detailed description of the method and analysis please refer to sections 2.5 and 3.1.7. The mean pH values of CIC-5 positive endosomes are depicted in Figure 49.

As described earlier, the expression of WT CIC-5 significantly reduced the endosomal pH. This was also the case for its mutants R516W, N408E and N408A. The WT, R516W, N408E mutant displayed a pH around 6 whereas the control cells showed a higher pH of 6.5. Additionally, the N408A CIC-5 mutation reduced the pH with an even higher magnitude than the WT (around pH 5.7). Although the measurement of endosomal pH in CIC-5 knockout mice (Hara-Chikuma et al., 2005), Dent's disease patients (Gorvin et al., 2013), or in cell culture (Alekov, 2015) indicated that mutations in CIC-5 result in more alkaline endosomal pH, the mutant R516W seemed to be functional to generate a WT-like pH in HEK293T cells.

Figure 49: WT CIC-5 and the mutants R516W, N408E and N408A promote acidification.

Analysis of vesicular pH of HEK293T cells transiently co-expressing WT, R516W, N408E, or N408A CIC-5-mCherry and synapto-pHluorin2 or solely expressing synapto-pHluorin2 (control). N=30 cells for CIC-5 WT, n=23 cells for R516W, n=21 cells for N408E, n=20 cells for N408A and n=26 cells for control. The results shown are means \pm SEM. * indicates a significant difference between two samples. The significance was tested using a One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05 .

3.5.6 Colocalization of WT, R516W, N408E, and N408A CIC-5 with Rab7

Following the evaluation of the endosomal pH, the question if the mutants were localized to late endosomes to a higher extend than the WT was addressed. Since the altered endosomal velocity of the Dent's and the glycosylation-deficient mutants might also be a result of a faster (or impaired) maturation of the endosomes. An increased velocity and a more acidic pH might indicate that the endosomes are transported faster to late endosomes (or recycling endosomes). In order to evaluate the maturation of the CIC-5 positive endosomes, the different CIC-5 constructs were cotransfected with Rab7, a marker for late endosomes (Feng et al., 1995) and a colocalization analysis was performed in HEK293T and MDCKII cells transiently expressing WT, R516W, N408E, or N408A CIC-5-mCherry (Figure 50). For the HEK293T cells, the colocalization analysis showed, in general, that there was a distinct overlap of Rab7 objects and objects of the different CIC-5 constructs. However, only very little CIC-5 objects colocalized with Rab7 (Figure 50 E, object based), but the few overlapping objects shared a high amount of colocalizing pixels (size based analysis). In MDCKII cells, on the other hand, there was a high colocalization coefficient between CIC-5 and Rab7 objects and vice versa (see Supplemental Figure 6). Here, Rab7 overlapped to nearly 100% with R516W objects and the overlapping area was also around 100%. Yet, there were only around 30% of R516W objects that colocalized with Rab7 (Figure 50 D). In both cell lines, none of the mutants showed a significantly different amount of overlapping objects, indicating that all CIC-5 variants are present on late endosomes to the same extend.

Figure 50: Colocalization of WT, R516W, N408E and N408A CIC-5 with Rab7 in HEK293T cells.

A-D) representative confocal images (single z-slides) of HEK293T cells transiently transfected with WT (**A**), R516W (**B**), N408E (**C**) or N408A (**D**) CIC-5-mCherry (in red) and cotransfected with Rab7-EYFP (in green). **E)** Box plots summarizing the results from object-based and size-based colocalization analysis corresponding to the number of overlapping objects defined in two channels as Rab5WT- or Rab5CA- and CIC-5-containing objects. N=10 cells for WT, R516W, and N408E, as well as n=9 cells for R516W, and N408A. Single cells (•), mean (■), and median (—). Scale bars correspond to 10 μ m

3.5.7 No altered fluid-phase and receptor mediated endocytosis in WT and mutant CIC-5

The altered endosomal motility might have been the result of, or might have been influenced by, an altered endocytosis rate. The loss or downregulation of CIC-5 was shown to impair albumin endocytosis in kidney proximal tubular cells (PTC) in Dent's disease and CIC-5 knockout mice (Christensen et al., 2003a; Piwon et al., 2000). In order to investigate the rate of receptor-mediated and fluid-phase endocytosis, the internalization of fluorescently labeled albumin and dextran was measured. Albumin has been established as a marker for receptor-mediated, clathrin-dependent endocytosis (Caruso-Neves et al., 2005; Schwegler et al., 1991; Takano et al., 2002) and dextran as a marker for fluid-phase endocytosis (Cao et al., 2007; Gorvin et al., 2013; Shurety et al., 1998). The internalization of Atto425-labeled albumin was previously examined in MDCKII cells transiently expressing WT, R516W, N408E, or N408A CIC-5. Albumin was internalized and partially overlapped with CIC-5 (see Supplemental Figure 5). Nontransfected HEK293T cells (=control) or cells transiently expressing WT, or the mutants R516W, N408E and N408A CIC-5 mCherry were first serum starved and subsequently incubated with either 50 µg/ml Atto425-labeled albumin or Atto488-conjugated dextran. The unbound albumin/dextran was washed off with trypsin and the fluorescence intensity (FI) per cell was analyzed.

The overexpression of CIC-5 caused a slightly increased internalization and thus increased endocytosis of albumin (Figure 51 A). The mutants R516W also showed a tendency towards a higher amount of internalized albumin and dextran, whereas N408E and N408A CIC-5 had a decreased endocytosis rate as compared to WT CIC-5 overexpressing cells. Yet, there were no significant differences between the control and the WT or the mutants. In the dextran uptake of the R516W mutant (see Figure 51 B) one sample showed three times more dextran fluorescence than the other two samples. Since no obvious reasons for the increased internalization of dextran in this specific sample could be detected; the sample was not excluded from the data.

Figure 51: Uptake of albumin or dextran is not altered in HEK293T cells transiently expressing WT, R516W, N408E and N408A CIC-5.

The endocytosis of fluorescently labeled albumin (**A**) or Atto488-conjugated dextran (**B**) in nontransfected HEK293T cells (control) or cells transiently expressing mCherry-tagged WT CIC-5 or the mutants R516W, N408E or N408A was measured. Therefore, cells were first serum-starved for 1 h before they were incubated for 5 min with 50 μ g/ml albumin or dextran at 37°C. The fluorescence intensity normalized to the cell density is shown (FI/OD₇₅₀). For albumin the FI at 524 nm (excited at 488 nm) is shown and for dextran the FI at 472 nm with an excitation at 425 is displayed. Single cells (*), mean (-) is depicted. N=3 petri dishes. One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05, but no significant differences were detected between the samples.

In conclusion, although the pH of WT, R516W, N408E, and N408A CIC-5 was significantly reduced, the fluid-phase and receptor-mediated endocytosis were not notably influenced in these cells. Furthermore, all CIC-5 variants were located to late endosomes in a similar manner.

4 Discussion

This study elucidated the function of the chloride/proton exchanger CIC-5 in the intoxication of TcdA, a toxin of the pathogenic bacterium *C. difficile*. Furthermore, tools to study endosomal motility were established and the movement of CIC-5 positive endosomes in terms of a possible influence of glycosylation of the CIC-5 protein was analyzed.

CIC-5 is broadly expressed in the kidney (Devuyst et al., 1999), brain, lung, liver (Steinmeyer et al., 1995), and gastrointestinal cells (Vandewalle et al., 2001). It is located in early to late endosomes, as well as on the PM and is crucial for acidification of endosomes and hence for the endocytosis process (Christensen et al., 2003b; Devuyst et al., 1999; Friedrich et al., 1999; Günther et al., 1998; Hara-Chikuma et al., 2005; Piwon et al., 2000).

C. difficile bacteria colonize a host's gut and disrupt the gastrointestinal epithelial barrier in order to spread to new hosts (Papatheodorou et al., 2010; Pruitt et al., 2010). Thereby, they cause severe, life-threatening diarrhea (McFarland et al., 1989; Papatheodorou et al., 2010). The toxins of *C. difficile*, TcdA and TcdB, enter the host cell via the endocytic route and require an acidic environment in order to get access into the cytosol where they inactivate Rho-GTPases (Barth et al., 2001; Papatheodorou et al., 2010; Voth and Ballard, 2005). Since CIC-5 is situated in gastrointestinal cells and is important for endocytosis, the first part of this study set out to investigate the possible role of WT CIC-5 and its non-transporting mutant E268Q CIC-5 in the context of intoxication of TcdA in HT-29 cells.

Since internalization of proteins depends on endocytosis and subsequent processing of endosomes, the second part of this study focused on the motility of endosomes. The study concentrated on the influence of CIC-5 glycosylation on the endosomal motility close to the PM. Multiple mutations in the *CLCN5* gene result in proteins that lack the complex glycosylation. Furthermore, their transport into endosomes and to the PM is inhibited as they are retained in the ER (Ludwig et al., 2005; Smith et al., 2009). Using the R516W CIC-5 as representative ER-retained, non-complex-glycosylated Dent's disease mutant, and two artificial glycosylation-deficient mutants (N408E and N408A), a tool was established to investigate endosomal motility.

4.1 The chloride/proton exchanger CIC-5 increases the susceptibility of HT-29 cells towards TcdA

Previous findings suggested that an overexpression of CIC-5 caused a higher cytopathic effect of TcdA and TcdB. In order to examine if the chloride/proton transport of CIC-5 is responsible for the increased cytopathic effect of TcdA, the non-transporting E268Q CIC-5 was used as control (Figure 11) (Ruhe et al., 2017). In this mutant, the proton glutamate is neutralized, abolishing the transport of protons and chloride ions (Grieschat and Alekov, 2012; Smith and Lippiat, 2010; Zdebik et al., 2008). However, the cytopathic effect of TcdA was increased in WT, as well as in E268Q CIC-5 expressing cells.

In order to exclude the aspect of artificial effects due to the overexpression of CIC-5, endogenous CIC-5 was knocked down in HT-29 cells by siRNA targeted against human CIC-5 in the present study. Cells were then intoxicated with TcdA and the cell rounding as a result of the cytopathic effect was determined. The cytopathic effect was reduced by approximately 10% by 10 or 20 nM siCIC-5 respectively, as compared to cells transfected with non-targeting siRNA (Figure 24). In order to detect cells that were transfected with siCIC-5, a plasmid carrying the CD8 antigen sequence was cotransfected. Commercial microbeads with an anti-CD8 antibody were then added to the cell mixture after intoxication and the cell morphology of cells covered with multiple beads was investigated (as illustrated in Figure 24 A). The cotransfection rate of siRNA and plasmid DNA is most likely not 100%, raising the question if the microbeads-marked cells were indeed transfected with siCIC-5 and thus had reduced CIC-5 RNA levels. The qRT-PCR for the analysis of the RNA downregulation indicated that the transfection efficiency of siCIC-5 was quite high: 70% of CIC-5 mRNA was downregulated in HT-29 cells transfected with 20 nM siCIC-5 (Figure 23). Since HT-29 cells are hard-to-transfect cells, the transfection efficiency of plasmid DNA was usually around 30% (data not shown). For the intoxication, as well as the quantitative RT-PCR, the sample included both transfected and non-transfected cells. The high downregulation of CIC-5 mRNA in transfected HT-29 cells therefore indicates that the efficiency of siRNA can be considered higher than of plasmid DNA. This, in turn, increases the probability of pLeu2-CD8 expressing cells to be also transfected with siCIC-5.

The fact, that the reduction of the cytopathic effect on CIC-5 knockdown cells caused a lower amount of morphological changes, supports the theory that CIC-5 is important for the intoxication of TcdA. It further indicates that the findings in CIC-5 overexpressing cells are not a mere side effect due to the overexpression.

4.1.1 WT and E268Q CIC-5 are located to early and early-to-late endosomes in HT-29 cells

TcdA is internalized and processed in endosomes (Keel and Songer, 2011; Pruitt and Lacy, 2012). CIC-5 has been described to be located to early endosomes in rat proximal tubular cells (Günther et al., 1998). However, only very little is known about its presence in the endocytosis pathway of HT-29 cells. Thus, at first, the expression and subcellular localization of CIC-5 as well as its presence in the endosomal pathway of HT-29 cells was examined (Figure 22 - Figure 29). In this model cell line, WT CIC-5 was expressed and present as complex-, core- and non-glycosylated proteins with sizes ranging from 90-120 kDa (Figure 21), which is in accordance to the literature (Jouret et al., 2004; Schmieder et al., 2007). Deglycosylated CIC-5 has been shown to be impaired in its cell surface expression (Schmieder et al., 2007), thus, the different glycosylation patterns of CIC-5 might represent the capability of the protein to be targeted to the PM in certain tissues, or to be retained in the ER or located to endosomes. In addition to HT-29 cells, the expression of CIC-5 in HEK293T cells was investigated. Here, CIC-5 was complex-, core- and non-glycosylated as well. However, the band of the core- and non-glycosylated protein was more pronounced in HEK293T cells than in HT-29 cells, indicating that CIC-5 is more efficiently matured in HT-29 cells. Tissue dependent differences in the glycosylation have already been reported for the CIC-5 homologue, CIC-3 (Schmieder et al., 2007). The primary results showed that WT and the non-transporting CIC-5 increased the cytopathic effect of TcdA (Figure 11) (Ruhe et al., 2017). Since the uptake of TcdA and TcdB depends on the host's endocytosis machinery (Florin and Thelestam, 1983; Henriques et al., 1987; as reviewed in Voth and Ballard, 2005), the localization of both WT and E268Q CIC-5 in the endocytic pathway in HT-29 cells was examined. Therefore, the colocalization of WT and E268Q CIC-5 with Rab proteins, which are considered as markers for different endosomal stages (Chavrier et al., 1990), was assessed. The colocalization analysis demonstrated that WT and E268Q CIC-5 were

both located to early, Rab5 positive endosomes. Furthermore, the WT was also targeted on early-to-late, Rab7-positive endosomes (Figure 25 and Figure 28). In more detail, around 25-30% of WT and E268Q CIC-5 colocalized with Rab5. Furthermore, the WT also overlapped with around 30 % with Rab7 or Rab4a objects (Figure 25, Figure 26, and Figure 28). The association of CIC-5 with Rab4a and Rab5 is in accordance with findings regarding the localization of endogenous CIC-5 in rat intestinal cells (Vandewalle et al., 2001). An overlap of CIC-5 and Rab7 has also been previously reported for mouse thyroid gland cells (van den Hove et al., 2006). The similar colocalization value of WT CIC-5 with Rab5 and Rab7-positive endosomes can be explained by the endocytosis pathway: During endosomal maturation, Rab5 positive endosomes become Rab7-positive late endosomes (Rink et al., 2005). Rab4a is also involved in early endosomes however it is located on a different endosomal compartment than Rab5. During maturation, Rab4a-positive endosomes become Rab11-positive recycling endosomes (De Renzis et al., 2002).

In conclusion, the results of this research indicate that WT and E268Q CIC-5 were mainly present in early endosomes and it shows that WT CIC-5 was also targeted to early-to-late and not to recycling endosomes of the endocytosis pathway in HT-29 cells. This suggests a role of CIC-5 in the sorting machinery and not in the recycling pathway.

4.1.2 CIC-5 colocalizes with the *C. difficile* toxin TcdA

In a next step, it was necessary to assess a possible colocalization of TcdA and CIC-5 in order to investigate if the increased cytopathic effect of TcdA was a side product of the CIC-5 expression. Such a possible side effect could be an overall increased endocytosis rate in CIC-5 expressing cells. Another theory was that TcdA may hijack CIC-5 either to get access to the host cell or to increase its toxicity in a different way. In order to investigate the last possibility, HT-29 cells overexpressing WT CIC-5 were intoxicated with EGFP-labeled TcdA and a colocalization analysis was performed (Figure 29). The living cell analysis (Figure 29) showed that 34% of TcdA colocalized with CIC-5. The colocalization on similar subcellular structures indicated that CIC-5 has a direct influence on the internalization of TcdA.

As a subsequent step, the kinetic of internalization was assessed and the colocalization of CIC-5 and TcdA during different internalization periods was analyzed (Figure 30). However, it was not possible to achieve this research goal, because there was nearly no intracellular TcdA detectable in the fixed cells. In contrast to living cells, in which TcdA was observed in vesicular-like structures, in fixed cells, TcdA appeared solely at the PM (Figure 31 for living cells, Figure 32 for fixed cells). One possible explanation for this finding is that the internalized EGFP-tagged TcdA could not be detected due to quenching or a severe reduction of the EGFP fluorescence intensity as a result of the fixation procedure. The problem that a fixation step can reduce the fluorescence intensity has already been described previously (Brock et al., 1999). In addition, Kern and Feig described a low fluorescence intensity of intracellular EGFP-tagged TcdA (Kern and Feig, 2011). The underlying mechanism of the reduced fluorescence intensity of EGFP at low pH is a protonation of the hydroxyl group of tyrosine at position 66 which probably results in a decreased molar absorption coefficient of the protein (Haupts et al., 1998). Thus, the small amount of EGFP-TcdA carrying endosomes in the living cells might be a result of the reduced EGFP-fluorescence intensity in endosomes that were more acidic. Labeling TcdA with the fluorescence dye Atto425, lowered the amount of colocalizing objects (only around 10% of colocalization was detected) but it circumvented the problem of the quenched or protonated EGFP. The low colocalization coefficient might be explained by the subcellular distribution of TcdA which was more diffuse compared to the EGFP-tagged TcdA (Figure 29 for internalized EGFP-TcdA, Figure 31 for the labeled Atto425-TcdA). The Atto425 NHS-ester dye labels primary amines (NH₂) groups of proteins. Thus, it labeled not only the full length toxin, but also protein fragments in the sample. This probably resulted in the diffuse subcellular localization and the higher amount of internalized toxin (or toxin fragments). The diffuse localization pattern also caused the lower overlapping rate in the samples with the labeled toxin compared to the EGFP-TcdA.

Overall, this study demonstrated a striking colocalization of TcdA and CIC-5, indicating that CIC-5 has a direct influence on the intoxication of TcdA.

4.1.3 CIC-5 promotes TcdA internalization and acidification of CIC-5 positive endosomes

There are three possibilities how CIC-5 could increase the toxicity of TcdA: i) the toxin could be internalized faster, ii) a higher amount of toxin could be internalized or iii) the internalized toxin is processed faster due to a lower endosomal pH.

In order to test for the first and second possibility, the amount of internalized (and membrane-bound) TcdA in CIC-5 overexpressing cells was investigated. Since the transporting capability of CIC-5 might be important for the toxin internalization, not only cells expressing the WT but also the non-transporting E268Q CIC-5 mutation were used. To examine the amount of internalized TcdA, HEK293 cells stably expressing WT or E268Q CIC-5 were intoxicated with TcdA and the toxins' fluorescence per cell was measured (Figure 32). Of note, stably transfected HEK293 cells were needed for this experiment because it was necessary for the analysis that all cells expressed WT or E268Q CIC-5 and the transfection rate of HT-29 cells was too low for this approach. Significantly more TcdA was internalized in WT and E268Q CIC-5 overexpressing cells as compared to the control (mCherry overexpressing cells). It is worth noticing, that there was also twice as much TcdA internalized in cells expressing WT CIC-5 than in the non-transporting mutant E268Q. Immediately after endocytosis, the chloride concentration in the vesicle raises from early to late endosomes (Sonawane et al., 2002) and CIC-5 was reported to be involved in endosomal chloride accumulation (Novarino et al., 2010). Hence, the reason for the reduced endocytosis in E268Q cells might be a result of a lower chloride concentration which leads to a decreased maturation of endosomes causing an impaired endocytosis rate. In order to determine the chloride concentration in WT and E268Q CIC-5 endosomes, further research is required. The present experiment was not able to distinguish between the first and second possibility for the increased TcdA toxicity that were proposed above. Internalization kinetics are necessary to differentiate between a higher amount of internalized toxin and a faster internalization rate by using different time periods for the internalization step followed by immediate fixation of the cells.

In order to address the third possibility, that the acidification of CIC-5 positive endosomes caused a faster processing of the toxin, the pH of endosomes was assessed. The endosomal pH of WT and E268Q CIC-5 positive endosomes was significantly lower than of the control cells (around pH 6 in CIC-5 and pH 6.5 in control cells), pointing to more progressed endosomes in CIC-5 overexpressing cells (see Figure 33). Surprisingly, the E268Q mutant was functional sufficient to generate a WT like pH. In a non-transporting mutant of CIC-7, a homologue of CIC-5, a functional vesicular acidification was shown as well (Weinert et al., 2014). The E268Q has been identified to increase the electric capacity of membranes (Grieschat and Alekov, 2012). In general, the acidification of endosomes is generated by the proton pump V-ATPase (as reviewed in Forgac, 2007). However, loss of CIC-5 is linked to a defect in endosomal acidification (Piwon et al., 2000; Silva et al., 2003; Wang et al., 2000), suggesting a role of CIC-5 in the acidification process. It has been proposed that the chloride/proton exchange function of CIC-5 directly activates the V-ATPase and thereby ensures normal acidification of endosomes (Sato et al., 2016). This stands in contrast to the findings in this study. Here, the non-transporting E268Q CIC-5 mutant had a WT-like endosomal pH. Possible explanations for the acidified endosomes in the E268Q mutant might be that CIC-5 activates regulators of the V-ATPase, or that the electric membrane capacity generated by CIC-5 activates the V-ATPase, thus promoting the proton transport into the vesicle. Furthermore, the E268Q mutant might transport one chloride (instead of two) at the expense of one proton, providing counter ions to maintain the function of the V-ATPase. However, more research is needed in order to determine whether any of the three proposed possibilities caused the decreased pH in E268Q CIC-5 cells.

In conclusion, the above mentioned findings indicate that the chloride/proton antiporter CIC-5 promotes an increased toxicity of the *C. difficile* toxin TcdA due to an accelerated maturation of endosomes. The lower pH may cause a faster pH-dependent conformational change of TcdA which, in turn, results in the endocytosis of a higher amount of TcdA and faster translocation of the catalytic domain into the cytosol. A faster cell entry due to a quicker conformational change at lower pH was shown for TcdB of a hypervirulent strain (Lanis et al., 2010).

4.2 The role of glycosylation in fine-tuning of CIC-5 mediated endocytosis

Internalization of proteins depends on the endocytosis machinery and includes the further processing and maturation of endosomes. The second part of this study set out to establish tools to investigate endosomal motility. Here, the focus was on the influence of CIC-5 glycosylation, since multiple mutations in the *CLCN5* gene result in proteins with an inhibited complex glycosylation. Furthermore, these mutations have an impaired transport into endosomes and to the PM, and cause the renal Dent's disease (Ludwig et al., 2005; Scheinman, 1998; Smith et al., 2009). The defects in the glycosylation combined with the ER retention of Dent's disease mutants led to the hypothesis that glycosylation of CIC-5 might have an effect on the trafficking of CIC-5 positive endosomes due to a reduced transport to or increased backhaul from the PM. Therefore, besides the WT CIC-5, the Dent's disease mutant R516W CIC-5 and two artificial glycosylation deficient mutants (N408E and N408A CIC-5) were examined. The choice for the R516W CIC-5 as a representative Dent's disease mutant was motivated by the fact that this mutant is the only, so far described, missense mutation exhibiting ER-retention with functional (however reduced) chloride currents. The chloride currents were reduced by 30 % compared to the WT, which is probably due to its lower cell surface expression (Ludwig et al., 2005; Smith et al., 2009).

4.2.1 R516W, N408E, and N408A CIC-5 have no complex glycosylation

Two putative N-glycosylation positions were predicted for human CIC-5: N408 and N38 (Figure 34). Since it was previously shown that N408 is the *bona fide* glycosylation site in human CIC-5 (Jouret et al., 2004; Schmieder et al., 2007), the glycosylation deficient mutants used in this work, were generated at this position.

First, it was necessary to assess the glycosylation patterns of WT and the three CIC-5 mutants. The glycosylation assay showed that the WT CIC-5 protein was present in a complex, and core- and non-glycosylation pattern with sizes ranging from 90-120 kDa. In contrast, all of the mutants (R516W, N408E, and N408A CIC-5) lacked the complex glycosylation (Figure 35).

The WT CIC-5 has been described to have a complex glycosylation pattern in human and mouse kidney (Jouret et al., 2004; Schmieder et al., 2007) as well as in *Xenopus* oocytes (Jouret et al., 2004; Schmieder et al., 2007). The lack of the complex glycosylation of the R516W CIC-5 has been described before as well (Smith et al., 2009).

Consequently, the subcellular localization of WT, R516W, N408E, and N408A CIC-5 was examined. Therefore, fluorescence microscopy of the mCherry tagged CIC-5 constructs in MDCKII cells was used and showed that WT CIC-5 was located to endosomes, the R516W mutant was situated in a few endosomes and to a higher amount in an ER-like structure, and the two glycosylation-deficient mutants N408E and N408A were also targeted to endosomes and to a smaller amount to an ER-like structure (Figure 36). The localization pattern of the WT CIC-5, that was detected in this work, is in accordance to the previously reported localization to the PM and intracellular vesicles in mouse kidney (Sakamoto et al., 1999) and rat intestinal cells (Vandewalle et al., 2001). The R516W mutant has previously been described as an ER retention mutant (Smith et al., 2009). In this study, however, using MDCKII or HEK293T cells, this mutant was also present on vesicular, endosomal-like structures, although to a minor degree than the WT. The two glycosylation deficient mutants (N408E and N408A) were also situated on the PM. In *Xenopus laevis*, a non-glycosylated CIC-5 mutant also showed a localization to the PM, however the surface expression was reduced due to a retrieval from the PM that was five times faster as compared to WT CIC-5 (Schmieder et al., 2007).

In general, the glycosylation assay is able to indicate if proteins are trafficked from ER to Golgi, as the complex glycosylation occurs in the Golgi compartment. Since the R516W and the two glycosylation deficient mutants showed no complex glycosylation but were targeted to endosomes, there may be an alternative processing pathway for these proteins. For instance, it is also possible that they are transported through the Golgi besides their missing N-linked glycosylation. This has been shown for other renal apical membrane proteins such as the rat sodium-dependent purine-selective nucleoside transporter (Mangravite and Giacomini, 2003).

And also for the mammalian NaSi-1 sulfate transporter (Regeer et al., 2007). Both proteins are transported through the Golgi or post-Golgi compartments even without a missing N-glycosylation.

Another explanation is that the overexpression of the CIC-5 variants caused a different localization. For CIC-6, a homologue of CIC-5 which is located on late endosomes, it was shown that overexpression resulted in a localization to early endosomes as well (Ignoul et al., 2007).

This study showed that CIC-5 is complex glycosylated and it underlined the previous findings that the asparagine at position 408 is the only N-glycosylation site in human CIC-5. This was indicated by the fact that the glycosylation deficient mutants (N408E and N408A) lacked the band in the SDS gel with the size of the complex glycosylation. Furthermore, the present study showed that the R516W CIC-5 had no complex glycosylation and an altered localization as compared to the WT.

Since the surface expression of the mutant CIC-5 might be altered, the PM expression of the different CIC-5 constructs should be examined using a biotinylation or chymotrypsin assay. Furthermore, a colocalization analysis with an ER marker could indicate if the R516W is indeed, more ER-retained than the other CIC-5 variants.

In conclusion, the R516W, N408E, and N408A CIC-5 had no complex N-glycans, whereas the WT CIC-5 protein was complex glycosylated. The fluorescence microscopy indicates that the WT, N408E, and N408A CIC-5 were located to endosomes and the PM. The R516W was also targeted to endosomes and to an ER-like structure. This suggests that the lack of N-glycans does not inhibit the transport of the CIC-5 protein into endosomes and to the PM.

4.2.2 Mutations affecting the glycosylation of CIC-5 influence endosomal mobility

In cells of the PT, CIC-5 is required for the uptake of LMW proteins and located mainly to early endosomes (Devuyst et al., 1999; Luyckx et al., 1998). In cells of the collecting duct in mice (Sayer et al., 2001), or transfected cells (Günther et al., 1998), CIC-5 is also located to the PM. For the transport of CIC-5 to the PM, the interaction with KIF3B, a kinesin motor, has been reported (Reed et al., 2010).

For the transport back into the cell, no motor protein was identified so far. However, for Rab5-positive early endosomes, the interaction with the motor protein dynein was identified for long inwards movements (Flores-Rodriguez et al., 2011).

For multiple Dent's disease causing CIC-5 mutations, the transport to the PM and into endosomes seems to be impaired, since their localization is mainly restricted to the ER. In addition, or maybe due to the low cell surface expression, their endocytosis rate is impaired (Gorvin et al., 2013). As mentioned before, many of these mutants have no complex glycosylation (Smith et al., 2009).

The next aim of this study was to examine the motility of CIC-5-positive endosomes close to the PM in order to determine if the transport to or from the PM of these endosomes might differ between the four CIC-5 variants. Therefore, TIRF microscopy with a field depth of 95 nm was used and time-lapse images of CIC-5-positive endosomes were recorded. All CIC-5 variants possessed vesicles that were transported along microtubules. The microtubule-dependent transport can be seen by the fact that adding nocodazole, a reagent which disrupts the microtubule network, resulted in the loss of long, far moving endosomes (Figure 37 A). This is in accordance with previous findings regarding the transport of endosomes along microtubule (Flores-Rodriguez et al., 2011).

First, it was unclear whether differences in the long or short living; slow or fast moving endosomes exist. Therefore, two different cycle times were used for the time-lapse imaging and recorded over different time periods. The high temporal resolution (= short cycle time) revealed more differences among the four CIC-5 constructs: The N408A remained close to the PM for the longest (in average 15.6 ± 0.13 seconds) and the R516W was the shortest (10.5 ± 0.13 seconds). Remarkably, the WT moved the furthest from its origin (0.84 ± 0.006 μm), whereas the N408A traveled the shortest distance (0.63 ± 0.004 μm) (see Figure 43 and Table 3). In terms of speed, the R516W had the fastest endosomes ($0.42 \pm 4.2\text{E-}4$ $\mu\text{m/s}$) and the WT the slowest (0.36 ± 0.001 $\mu\text{m/s}$). The diffusion coefficient was the highest for the N408E (0.018 ± 0.002 $\mu\text{m}^2/\text{s}$) and the smallest for the N408A ($0.009 \pm 9.2\text{E-}4$ $\mu\text{m}^2/\text{s}$) (see Table 3, Figure 45, and Figure 47).

The target-orientation of the endosomal walk correlated well with the net displacement: WT and N408E endosomes moved more straightforward in one direction than R516W and N408A (Figure 48).

All four CIC-5 constructs showed a variety of different motilities: Endosomes of the WT moved slowly, more directly along the PM for a long time, either looking for a place to fuse with the PM, or for other endosomes to fuse with. The R516W possessed endosomes that quickly exited the measured field or fused with the PM or other endosomes. Thereby, the endosomes did not move far away from their origin and walked less target-oriented. The N408E had the same motilities like the WT. However, the N408A had endosomes that moved the slowest and least far from their origin. Furthermore, they walked less target-oriented and were present at the PM for a longer time which indicates that they fused less with the PM or other endosomes and were not transported fast further into the cell (Figure 47).

Confocal images indicated that the R516W is present at the PM to a smaller amount as compared to the WT (Figure 36). In combination with the above mentioned faster velocity and shorter time spend close to the PM of the R516W CIC-5, it is possible that this mutant is faster transported from the PM into the cell than the other CIC-5 variants. The PM expression of R516W has been described to be lower than in the WT due to a retrieval of the protein from the PM that was five times faster than the WT (Ludwig et al., 2005; Smith et al., 2009).

Astonishingly, the two glycosylation-deficient mutant showed a different motility as compared to the R516W. The N408E endosomes had a similar motility like the WT, whereas endosomes of the N408A moved different as compared to the WT. The fact that the two glycosylation-deficient mutants behaved differently as compared to each other suggests that, primarily, the lack of N-glycans is not the reason for the altered endosomal motility. The altered motility of N408A endosomes may be a result of an impaired interaction with motor proteins. The cell surface expression of CIC-5 has been reported to be dependent on its interaction with KIF3B (Reed et al., 2010).

In general, early and late endosomes have been reported to be transported along microtubules by dynein-1 (Flores-Rodriguez et al., 2011; Zajac et al., 2013) and kinesin (Chen et al., 2008; Schuster et al., 2011). Thus, the long lifetime and slow velocity of the N408A may be a result of either a dissociation of the motor protein from N408A CIC-5 endosomes or a reduced binding capability of both proteins. This might be due to an altered conformational change of N408A CIC-5 which was caused by the mutation.

For future research to determine if an impaired interaction with motor proteins, such as KIF3B or dynein, is the underlying mechanism of the altered endosomal speed, interaction studies of CIC-5 positive endosomes *in vitro* might give some insights. Furthermore, the effect of dynein or kinesin depletion on the motility of CIC-5 endosomes should be examined, either by using knockdown cell lines or inhibitors such as the small molecule ciliobrevins (for dynein) (Roossien et al., 2015). In addition, the establishment of the particle tracking method also indicates that in order to examine differences between the motility of endosomes, choosing the correct circumstances for time-lapse imaging recording, such as cycle time, length of the recording need to be evaluated as they can severely influence the results.

In conclusion, R516W and N408A CIC-5 showed altered endosomal motilities as compared to the WT and N408E CIC-5. The Dent's mutant R516W was probably retrieved faster from the PM than the WT and transported quickly further into the cell. The N408A CIC-5 had endosomes which moved slowly and less target-oriented along the PM as compared to the WT but were not quickly retrieved from or fused with the PM or other endosomes. This indicates that the glycosylation status alone does not influence the trafficking of CIC-5 positive endosomes. It is more likely, that differences in the conformation of the protein caused by the mutations, impairs the interaction of CIC-5 with motor proteins, or even the integrity of CIC-5 in membranes.

4.2.3 WT and mutant CIC-5 promote acidification, are located to late endosomes and have no impaired endocytosis

The altered motility of the mutant and WT CIC-5 variants might also be caused by a changed function of CIC-5 such as a changed endosomal pH which can also effect the maturation of endosomes. Therefore, this study further investigated the endosomal pH of WT, R516W, N408E, N408A CIC-5 and it showed that they all promoted acidification (Figure 49). The N408A was also located on endosomes that were even more acidic than the WT (pH 5.7 compared to the WT with a pH of 6.1). The pH of early endosomes was reported to be around 6.3 in mammalian cells and around 5.5 in late endosomes (as reviewed in Casey et al., 2010).

Whole cell currents of R516W CIC-5 in HEK-MSR cells as well as in *Xenopus laevis* oocytes are severely reduced as compared to WT CIC-5 currents (Ludwig et al., 2005; Smith et al., 2009), indicating an impaired function of the mutant CIC-5. However, it is also possible that the differences in the chloride currents are due to the low expression of R516W at the PM. In this study, all CIC-5 mutants were sufficiently functional to promote endosomal acidification.

During endosomal transformation from early to late endosomes, protons are accumulated in the endosome, reducing its pH (Hurtado-Lorenzo et al., 2006; Stauber and Jentsch, 2013). Therefore, the low pH of N408A positive vesicles might indicate that this mutant is situated on late endosomes or is transported faster through the endosomal pathway. The colocalization analysis with Rab7-marked, late endosomes, showed no differences between WT and mutant CIC-5 in HEK293T and MDCKII cells (Figure 50 for HEK293T cells, Supplemental Figure 6 for MDCKII cells). A distinct colocalization of CIC-5 on late endosomes has been previously shown in mouse thyroid gland cells (van den Hove et al., 2006). In order to determine if the ratio of early to late endosomes was altered in any of the used CIC-5 variants, an additional colocalization analysis with Rab5 as marker for early endosomes needs to be performed. Furthermore, it would be interesting to examine the localization to recycling endosomes as well. The pH in endosomes decreases from early to late endosomes, but mildly increases in the recycling endocytic pathway (Gagescu et al., 2000; Yamashiro et al., 1984).

Therefore it is more likely that the more acidic N408A is situated on late endosomes instead of recycling endosomes. However, the pH is not the only evidence for increased endosomal maturation. Besides proton accumulation, the chloride concentration also increases from early to late endosomes (Gerasimenko et al., 1998; Sonawane and Verkman, 2003). A combination of a chloride-sensitive and a pH-sensitive fluorophore (similar to the approach of Sonawane et al., 2002), might give more insights into the proton and chloride accumulation of WT, R516Q, N408E, and N408A CIC-5 positive endosomes.

Overall, the observed results indicate that none of the mutant CIC-5 variants used in this work was targeted to late endosomes in a higher amount than the WT.

Since Dent's disease is characterized by an impaired receptor-mediated endocytosis (Gorvin et al., 2013), the receptor-mediated and fluid phase endocytosis rate were examined. Therefore, albumin was used as a marker for the receptor-mediated and dextran as marker for fluid phase endocytosis, respectively (Cao et al., 2007; Caruso-Neves et al., 2005; Gorvin et al., 2013; Schwegler et al., 1991; Shurety et al., 1998; Takano et al., 2002). Neither the amount of internalized albumin nor dextran was altered in cells overexpressing R516W, N408E, or N408A CIC-5 as compared to WT CIC-5 overexpressing cells (Figure 51). Furthermore, the control cells (= untransfected cells) did not show a different amount of internalized albumin or dextran as compared to cells overexpressing the different CIC-5 variants. The fact that the control cells showed no differences to the WT CIC-5 overexpressing cells is in contrast to the reported crucial function of CIC-5 in endocytosis: In CIC-5 knockout mice, the endocytosis of albumin has been shown to be impaired (Hara-Chikuma et al., 2005; Piwon et al., 2000; Wang et al., 2000). The defects in the endocytosis of albumin are probably due to an impaired interaction of CIC-5 with cofilin, an actin-associated protein regulating the uptake of albumin (Hryciw et al., 2003). So far, the endocytosis rate in overexpressing CIC-5 HEK293T cells has not been determined. In order to gain more insights into the endocytosis rate of WT, R516W, N408E, and N408A CIC-5 further endocytosis assays are required with longer incubation times and as control, the endogenous CIC-5 mRNA levels need to be downregulated using siRNA.

In conclusion, the endosomal pH of WT, R516W, N408E, and N408A was more acidic than in control cells, indicating a sufficient function in promoting endosomal acidification. The N408A showed an even lower pH than the WT, suggesting that this mutant might be trafficked more pronounced towards late endosomes. However, a colocalization with Rab7-positive, late endosomes, showed no differences between WT and the three mutant CIC-5. In addition, the receptor-mediated and fluid-phase endocytosis was not altered in WT, R516W, N408E, and N408A CIC-5 overexpressing cells as compared to the control cells. This indicates that the glycosylation status of CIC-5 does not influence the maturation of CIC-5 positive endosomes or the endocytosis rate.

4.3 Summary and conclusions

In summary, this study demonstrated a new role of CIC-5 as a promoter for intoxication of toxins from *C. difficile*, by increasing toxin internalization and processing by acidifying endosomes. Thus, it causes a faster maturation of TcdA. This effect was not dependent on the chloride/proton exchange function of CIC-5, as the non-transporting mutant E268Q CIC-5 was still able to acidify endosomes to a WT-like pH. However, the transporting function is probably necessary for the normal endocytosis rate. In addition to the effect of CIC-5 on TcdA's toxicity, new insights on the motility of CIC-5 positive endosomes were gained by developing tools to study the movement of CIC-5 endosomes. The Dent's disease causing mutant R516W CIC-5 showed endosomes that were present close to the PM for a shorter time and moved with a faster speed and less target-oriented than the WT. However, this was most likely not caused by the lack of the complex glycosylation of this mutant. This is indicated by the analysis of the two artificial glycosylation-deficient mutants, N408E and N408A CIC-5. Both mutants had different motilities with the N408E being similar to the WT. Yet, endocytosis, endosomal pH and localization to late endosomes were unaltered in the mutants compared to the WT. Since the endosomal processing was normal in the mutants as compared to WT CIC-5, it is possible that conformational changes caused by the mutations led to an impaired interaction with motor proteins which, in turn, resulted in the altered endosomal motility. The so established particle tracking analysis leads the way for further studies such as the analysis of fusion events of CIC-5 positive endosomes with the PM.

Furthermore, tracking endosomes of CIC-5 and motor proteins simultaneously can give information about the interaction of WT or mutant CIC-5 with this motor protein.

In conclusion, ion transporters such as CIC-5 are possible targets for pathogens to gain access into the host's cell or to promote the pathogens virulence. Furthermore, the motility of endosomes is highly sensitive towards changes in proteins targeted in endosomal membranes. By understanding the exact mechanisms behind the intoxication of bacterial toxins and the motility of endosomes in the endocytic pathway, possible targets for drugs curing CDI or Dent's disease can be found.

5 Appendices

5.1 Materials

5.1.1 Chemicals, buffers, solutions and equipment

Unless stated otherwise, all chemicals were purchased from Invitrogen, USA, Carl Roth (Karlsruhe), Sigma-Aldrich (Steinheim), Merck (Darmstadt, Applichem (Darmstadt). Consumables were obtained from

Supplementary Table 1: Chemicals used in this work.

Name	Company
8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS)	AnaSpec, Inc
EndoH _r	New England Bioscience
FBS	Gibco/Life Technologies, USA
Formaldehyde 16 % (w/v), Methanol-free	Pierce™
Genitcin, G418	Invitrogen, USA
Glas cover slips	
L-Glutamine	Invitrogen, USA
Nigericin Sodium Salt	A.G. Scientific, Inc./ MoBiTec
penicillin/streptomycin	Invitrogen, USA
Petri dish	
PNGase F	New England Bioscience
Poly-L-lysine	Sigma-Aldrich, Germany

Supplementary Table 2: Solutions and buffers used in this work.

Name	Recipe or Company
0.25 % Trypsin-EDTA	Gibco/Life Technologies, USA
2x HEBS	274 mM NaCl, 40 mM HEPES, 12 mM Dextrose, 10 mM KCl, 1.4 mM Na ₂ HPO ₄ , pH 7.05
5x SDS loading dye	3% SDS, 2% glycerol, 0.02% Bromphenol blue
DPBS (+Mg and Ca)	Gibco/Life Technologies, USA
FBS	Gibco/Life Technologies, USA
Fixation solution	4% PFA in PBS
Fluoromount-G®	Southern Biotechnology Associates, Inc.
hypoosmotic buffer	150 mOsm, Tyrode's solution diluted 1:2

Lyse buffer	150 mM NaCl, 10 mM HEPES, 1% Triton-x, 1% vol Roche complete Protease Inhibitor Cocktail (freshly added)
PBS (-Mg and Ca)	Lonza, Switzerland
pH-buffer	Tyrodé's solution pH 6-8
SDS-running buffer	
TcdA buffer	20 mM Tris, 50 mM NaCl, pH7.4
Tyrodé's solution	150 mM NaCl, 5 mM KCl, 1 mM MgCl ₂ , 10 mM HEPES, pH 7.4

Supplementary Table 3: Cell lines and cell culture medium.

Cell line	Medium recipe and origin
HEK293 and MDCKII	Eagle's medium (MEM) (Gibco/Life Technologies, USA), supplemented with 10% FBS and 900 µg/ml G418
HEK293T	DMEM (Gibco/Life Technologies, USA), supplemented with 10% FBS, 2 mM L-glutamine and 50 units/ml penicillin/streptomycin
HT-29	Dulbecco's MEM/ Hams F-12 (Biochrom, Germany), supplemented with 50 units/ml penicillin/streptomycin and 10% FBS

Supplementary Table 4: Kits used in this work

Name	Company
jetPRIME transfection Reagent	Polyplus-transfection, France
Atto 425 Protein Labeling Kit	Jena Bioscience
Lipofectamine 2000/Lipofectamine 3000	Thermo Fisher Scientific, USA
PD Sephagex G25 spin cloumn	GE Healthcare
QuickChange Site-Directed Mutagenesis Kit	Agilent Technologies

Supplementary Table 5: Equipment used for this work.

Name	Trade label and origin
Benchtop refrigerator	Enviro-Genie, Scientific Industires, Inc.

CIC-5 rev	GCAAAGAATGAACGCCACAAT
PGK1 forw	GAGATGATTATTGGTGGTGGAA
PGK1 rev	AGTCAACAGGCAAGGTAATC

5.5 Parameters used for the colocalization analysis with SQUASSH

Supplementary Table 10: Parameters used for the colocalization analysis. Standard deviations (stddev) of the point-spread function model (PSF) is given in pixel.

Parameter	Fixed cells	Live cells
Background removal	true	true
Window size	10	10
Stddev PSF xy	0.85	0.85
Stddev PSF z	0.79	0.79
Regularization	0.01	0.05
Min intensity channel 1	0.05	0.05
Min intensity channel 2	0.05	0.05
Subpixel	true	true
Cell mask channel 1	true	true
Cell mask channel 2	true	true
Mask threshold channel 1	0.1683 for 0 min 0.1349 for 8 min 0.0475 for 15 min	0.0771
Mask threshold channel 2	0.0161 for 0 and 8 min 0.062 for 15 min	0.0459
Intensity estimation automatic noise model	Poisson	Poisson

5.6 Supplemental Figures

Supplemental Figure 1: Densitometric analysis of SDS-gel of proteins from WT, R516W, N408E, or N408A proteins.

The intensity of bands on the SDS-PAGE in Figure 30. Profile plots of each lane of one protein gel are depicted.

Supplemental Figure 2: Lifetime, net displacement and mean velocity of all trajectories of the different CIC-5 constructs in low temporal resolution.

The lifetime (**A, D**), net displacement (**B, E**) and mean velocity (**C, F**) of all trajectories were extracted. **A-C** shows the histograms of binned data and **D-F** displays the mean values \pm SEM of all trajectories from all measured cells. WT CIC-5 is displayed in blue, R516W in green, N408E in cyan and N408A in red. N=34138 trajectories for WT, n=15850 trajectories for R516W, n=55048 trajectories for N408E and n=25127 trajectories for N408A. For the histograms, the data was binned in 41 bins for the lifetime and 50 bins for net displacement and mean velocity. * indicates a significant difference between two values. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05.

Supplemental Figure 3: Lifetime, net displacement and mean velocity of all trajectories of the different CIC-5 constructs in high temporal resolution.

The lifetime (A, D), net displacement (B, E) and mean velocity (C, F) of all trajectories were extracted. A-C shows the histograms of binned data and D-F the mean values \pm SEM of all trajectories. WT CIC-5 is displayed in blue, R516W in green, N408E in cyan and N408A in red. N=27320 trajectories for WT, n=14192 trajectories for R516W, n=37106 trajectories for N408E, and n=29068 trajectories for N408A. For the histogram, data was binned in 46 bins for the lifetime, 50 bins for net displacement and 48 bins for mean velocity. * indicates significant difference between two values. Significance was tested using the One-way Anova with post-hoc Tukey HSD and significance was set at a P value of <0.05

Supplemental Figure 4: Velocity and displacement of particles from low and high temporal resolution.

Endosomes of MDCKII cells transiently expressing WT (blue), R516W (green), N408E (cyan), or N408A (red) CIC-5 mCherry were recorded in a TIRFM and their endosomes were tracked. Two different cycle times were used: one second (low temporal resolution, left lane) and 302 milliseconds (high temporal resolution, right lane). The velocity and displacement of each particle from frame to frame were analyzed of all measured cells. Please note, for this analysis, all detected endosomes of all trajectories are shown. In all other analyses, only endosomes that were detected for more than 3 frames were taken into account. For the low temporal resolution $n=90755$ particles for the WT, $n=61705$ for R516W, $n=143352$ for N408E, and $n=69256$ for N408A. For the high temporal resolution $n=64234$ particles for the WT, $n=74898$ for R516W, $n=74910$ for N408E, and $n=80071$ particles for N408A. Data was binned in 27 bins.

Supplemental Figure 5: Uptake of Albumin in MDCKII cells expressing WT, R516W, N408E, and N408A CIC-5. Representative images of MDCKII cells transiently expressing WT (A), R516W (B), N408E (C), or N408A (D) CIC-5 mCherry (red) were incubated with 50 nM albumin (green) labeled with Atto425 for 2.5 h. Single z-slides are shown and scale bar represents 10 μ m.

Supplemental Figure 6: Colocalization of WT, R516W, and N408E CIC-5 with Rab7 in MDCKII cells.

Representative confocal images (single z-slides) of MDCKII cells transiently transfected with WT (**A**), R516W (**B**), or N408E (**C**) CIC-5-mCherry (in red) and cotransfected with Rab7-EYFP (in green). **E**) Box plots summarizing the results from object-based and size-based colocalization analysis corresponding to the number of overlapping objects defined in two channels as Rab7 and CIC-5-containing objects. N=4 cells for WT, n= 9 cells for R516W, and n=8 cells for N408A. Single cells (•), 25 – 75 % (□, large box), mean (■), median (—) as well as 99 % and 1 % (X)). Scale bars correspond to 10 μ m

6 Acknowledgement

First of all, I would like to thank my supervisor, Dr. Alexi Alekov, for giving me the great opportunity of working on the projects in his laboratory. I am very grateful for his intellectual support, his ideas and suggestions for the research projects.

Furthermore, I would like to thank Prof. Gerhard Ralf, for providing me with helpful information about the pathophysiology of TcdA and his support during the paper manuscript writing and revision process.

In addition I thank Dr. Andre Zeug for sharing his great knowledge about microscopy techniques and for providing some of the MATLAB scripts.

During the last few months of writing I felt incredible well supported and motivated, especially by Dr. Martin Fischer. I am thankful for his helpful input regarding my thesis, and his support in several other aspects at work.

My special thanks goes out to doctores Jeanne de la Roche, Daniel Wojciechowsky, Alexander Wirth, Josephine Labus and Yvonne Schill who gave me great input during the writing process of the thesis and who made life in the lab more pleasant😊. Thank you Dr. Matthias Grieschat for all the good music😊.

Next, I would like to thank Petra Kilian and Birgit Begemann for their superb technical and personal support. They motivated me throughout the years and helped me through tough times 😊.

Thanks to all members of the Institute of Neurophysiology, the atmosphere was always welcoming and supporting.

Thanks to Jan Bleidorn for counting cells 😊.

A very special “Thank you” goes out to the Cat Empire, Bliss n Eso, and Jamie Macdowell + Tom Thum. Their music always got me in a good mood and motivated me to sit down and “write one more paragraph”.

Most of all I would like to thank my family for always having my back.

8 Lebenslauf

Persönliches

Geburtsdatum, -ort:

23.01.1986, Paderborn

Karriere und Bildung

seit 11/2017

Institut für Biophysik, Leibniz Universität Hannover

11/2013-05/2017

Medizinische Hochschule Hannover

Doktorandin am Institut für Neurophysiologie, in der Arbeitsgruppe von Prof. Dr. Molekulare Physiologie.

2010 – 2012

Georg-August Universität Göttingen

Master of Science in Microbiology and Biochemistry
Titel der Arbeit: Steryl ester hydrolysis during germination in *Arabidopsis thaliana*

2006 - 2010

Julius Maximilians University Würzburg

Bachelor of Science in Biologie
Titel der Arbeit: Generation of an akuA deletion mutant and a deletion fragment for the vosA gene in *Aspergillus fumigatus*

1996 - 2005

Gymnasium Achern

Abitur

Praktika

12/2012 - 2/2013

Georg-August University Göttingen

Abteilung Biochemie der Pflanze, Albrecht-von-Haller Institut für Pflanzenwissenschaften

Projekt: Analysis of putative steryl ester lipases in *Arabidopsis thaliana*

04/2010-06/2010

Eskitis Institute, University of Brisbane, Australia

Projekt: Investigation of genes correlating with rasGRPase SH3 domain-binding protein 2 in breast cancer cells

10/2009-12/2009

Georg-August Universität Göttingen

Abteilung für molekulare Mikrobiologie und Genetik
Learning basic molecular and genetic tools for working with *Aspergillus fumigatus*

Hannover, 05 März 2018

Frederike Ruhe

9 List of publications

Original article:

Ruhe, F., Olling, A., Abromeit, R., Rataj, D., Grieschat, M., Zeug, A., Gerhard, R., and Alekov, A. (2017). Overexpression of the Endosomal Anion/Proton Exchanger CIC-5 Increases Cell Susceptibility toward *Clostridium difficile* Toxins TcdA and TcdB. *Front. Cell. Infect. Microbiol.* 7.

Poster:

Uptake of *Clostridium difficile* toxins A and B is facilitated by the endosomal anion/proton exchanger CIC-5. R. Gerhard, F. Ruhe, L.-A. Beer, R. Abromeit, A. Alekov

Presented at the 2nd GERMAN PHARM-TOX SUMMIT in March 2017 at Heidelberg.
